One strength of this study is that breast cancer anxiety among women who were invited to the mammographic screening can be compared with that of women who were not invited. Another is that reasons for nonattendance could be evaluated without taking the monetary cost of the mammogram into account.

One limitation of this study is the possibility of recall bias. Another is that the survey instrument was not of sufficient depth to explore the relationship of cancer anxiety to other related health-belief concerns. Nevertheless, our results, which suggest that anxiety about breast cancer may motivate attendance at breast cancer screening, are in accordance with other studies, which used survey instruments that focused on more attitude and belief dimensions—such as perceived susceptibility—than ours did.[20-22]

This study reveals a higher attendance rate than do most of the studies reviewed by Vernon et al.[23] The high acceptance may be due to the fact that the mammography screening was put in a broader context of a comprehensive health survey. Our results also reflect the fact that women living or working in the city center had easier access to the mammogram screening facility than those who did not. This inference of inconvenient locations as a significant factor in explaining nonattendance has been proposed in previous studies.[14,17,24]

We do consider the low response rate among nonattenders eligible for the study to be a limitation. The same problem was revealed in the study by Baines et al.[14] Although the 178 nonattenders may not be representative of all the women who declined, their answers should be of value in understanding reasons for nonattendance.

Our finding that 11% found the screening examination somewhat painful is in accordance with that of Baines et al.[14] but in contrast to that of Stomper et al., who found that only 1% reported the examination to be painful.[25] That more women in the FP group than in the SN group perceived the screening examination to be both painful and unpleasant may be because women in the FP group have breasts that are more difficult to examine due to size or density, thus necessitating a stronger and more painful compression of the breasts. These results indicate some drawbacks of screening that have also been revealed in other studies.[13]

The present study indicates that women who were anxious before the screening were more likely to remain so. Discouragingly, perceived adequate information does not seem to prevent anxiety about breast cancer among those who had to go through a workup examination. Additional measures need to be found to minimize this negative effect of the screening.

Nearly all the women taking part in the present study reported that they would attend another mammography screening and also recommend a screening to their friends. These results reflect a positive attitude toward mammography and a willingness to participate that has not been adversely affected by screening experiences. □

Medicaid Coverage of Screening Tests for Breast and Cervical Cancer

Leslie P. Boss, MPH, PhD, and Frederick H. Guckes

ABSTRACT

Although most women receive periodic Papanicolaou smear (Pap) for early diagnosis of cervical cancer, those who do not are more likely to be of lower socioeconomic status. Similarly, for the many women who do not receive periodic mammography for early diagnosis of breast cancer, cost has often been cited as a reason. Medicaid provides health benefits to roughly 9.4 million women of the appropriate ages for Pap tests and roughly 3.3 million women of the appropriate ages for mammography. The decision to provide such coverage is made on the state level. Of the 50 states and the District of Columbia, 49 provide some level of coverage for Pap smears, 39 for screening mammography. Knowing the extent of coverage allows public health professionals to take advantage of this funding source to provide services for lower-income women and may help initiate coverage in those states where it is not currently available. (*Am J Public Health.* 1992;82:252–253)

Introduction

Mammography coupled with physical breast examination and the Papanicolaou smear (Pap) are accepted screening tools for breast and cervical cancer, respectively, but not all women receive these tests at recommended intervals. A substantial barrier for routine screening is cost, and poor women are less likely to receive the tests at recommended intervals than are other women.[1]

The Medical Assistance Program, or Medicaid, mandates coverage of diagnostic and certain preventive services but not of breast and cervical cancer screening. Beyond services mandated by law, those covered by Medicaid are defined by each state based on a list of optional services. Medicare coverage, defined nationally, includes both screening mammography and Pap exams. Many elderly persons are eligible for coverage by both Medicaid and Medicare. When dual coverage exists, Medicare takes precedence.

Based on the per capita income of a state, federal Medicaid funds are available to match state expenditures. In 1989, the federal share ranged from 50% to 78%.[2] As benefits such as screening mammography are added to a state's Medicaid program, the state is responsible for payment and receives matching federal funds at the preassigned matching rate.

Knowledge of individual state practices regarding coverage of screening tests for breast and cervical cancer is important information for health practitioners and program planners. It can also be of value in efforts to mobilize support for increasing existing benefits.

Methods

A person responsible for cancer control activities in health agencies in each state (including the District of Columbia in this category) was asked about Medicaid coverage for screening for his or her state's population. When additional information was needed, the state Medicaid office was also contacted. General Medicaid statistics were obtained from the Health Care Financing Administration (HCFA). Because age-specific enrollment for females was not readily available for all states, the age distribution of all females in states reporting to CFA was applied to the total HCFA estimate of female Medicaid recipients to obtain estimates of the number of recipient females in the age groups of interest. The estimated numbers of screening-eligible women for whom Medicaid-financed screening coverage could be provided in each state were summed to estimate the total number of screens that could occur and be covered, given current Medicaid regulations.

Results

In 1989, there were approximately 24 million Medicaid recipients, 15 million (63%) of whom were female. Of all female recipients, approximately 9.4 million (64%) were aged 15 to 84 years, roughly corresponding to American Cancer Society guidelines for Pap smear screening. Similarly, roughly 3.3 million female Medicaid recipients (22%) were between the ages of 45 and 84, ages appropriate for routine mammographic screening.

Twenty-seven states allow coverage of Pap smears as a screening tool for all women eligible for Medicaid (Table 1). In another nine states and the District of Columbia, Pap smears are covered only with a physician's order. In five states, only the laboratory cost of the Pap smear is covered. In seven states, representing 22% of the total US population, women of childbearing age seen in family planning or maternity clinics are eligible for Medicaid coverage of Pap screening. Two states (2.8% of the US population) provide no coverage for screening for cervical cancer. It is estimated that there are 680 000 Medicaid eligible women for

whom even partial payment for a Pap exam is not covered.

In 23 states, coverage of screening mammography is provided for all Medicaid-eligible women; in an additional 15 states and the District of Columbia, coverage depends on a physician's order (Table 2). These 38 states represent 72% of the US population. No coverage is provided in 12 states. It is estimated that there are 570 000 Medicaid-eligible women ages 45 to 84 in these 12 states for whom mammography is not covered.

Legislation requiring third-party payors to provide coverage of screening for breast and cervical cancer exists in 33 and 8 states, respectively. The availability of Medicaid coverage in these states is shown in Tables 1 and 2.

[a]Includes the District of Columbia.
[b]States in bold print do *not* have any legislation related to third-party payment for screening mammography.

Discussion

The current interest in and awareness of early detection of breast cancer has led to increased use of mammography, changes in payment practices, and legislative and regulatory activity at both the state and national levels.

Payment for diagnostic tests and appropriate follow-up care for cancer are generally covered by Medicaid, whereas screening procedures frequently are not adequately covered. However, expenditures for treatment of cancer can be decreased by cost-effective use of screening tests.[3,4] It is not known how many screening procedures have been described as diagnostic tests so that costs would be covered under current regulations.

Medicaid is one of many third-party payors of medical care. Third-party payment laws vary considerably in their mandate. In this assessment of coverage, we chose to include all existing legislation, given that such legislation signifies a certain level of consciousness in that legislative body concerning the importance of cancer screening.

In 1990, Congress passed Public Law 101–354, Preventive Health Measures with Respect to Breast and Cervical Cancers. A major part of its purpose is "to screen women for breast and cervical cancer as a preventive health measure," "to provide appropriate referrals for medical treatment of the women screened," and "to ensure, to the extent practicable, the provision of appropriate follow-up services."[5] The law is meant to provide a payment of last resort; it is not to pay for a service for which payment can be made by any other state or federal compensation or health benefits program such as Medicaid or Medicare or under any other insurance or prepaid program. The law requires that low-income women be given priority for these services. Unfortunately, implementation of this act will be gradual, as appropriations to support the law will be incremental.

Low-income women are particularly in need of opportunities for early diagnosis of cancer. Appropriate screening results in improved survival. Thus, legislators, caregivers, and public health professionals alike need to maximize the use of the benefits available to millions of American women through such government compensation programs as Medicaid. □

Distribution of HIV Type 1 Infection in Childbearing Women in California

Frank J. Capell, BA, Duc J. Vugia, MD, MPH, Virginia L. Mordaunt, BA, William D. Marelich, MA, Michael S. Ascher, MD, Alan I. Trachtenberg, MD, MPH, George C. Cunningham, MD, Stephen S. Arnon, MD, and Kenneth W. Kizer, MD, MPH

ABSTRACT

The incidence of acquired immunodeficiency syndrome (AIDS) is increasing among California heterosexuals and children. To assess human immunodeficiency virus (HIV)-1 infection in childbearing women, we conducted a blinded serosurvey of newborns. Dried blood specimens taken from 99% of California births during the third quarter of 1988 (n = 135 808) and linked only to maternal demographic categories were tested for HIV-1 antibody by enzyme immunoassay and confirmed by Western blot. Period prevalence of HIV-1 infection was 7.4 per 10 000 childbearing women. Prevalence was highest for Black women and was also elevated for Hispanic and San Francisco Bay Area women. Findings suggest that California Hispanic women will make up an increasing proportion of new AIDS cases. (*Am J Public Health.* 1992;82:254–256)

Introduction

In California, acquired immunodeficiency syndrome (AIDS) and human immunodeficiency virus (HIV)-1 infection associated with heterosexual contact, injection drug use (IDU) among heterosexuals, and perinatal transmission are occurring with increasing frequency.[1] To assess HIV-1 infection levels in women of reproductive age, we conducted an unlinked survey of HIV-1 antibody prevalence in blood specimens taken from all newborns in California over a 3-month period. Seropositivity in such specimens indicates maternal HIV-1 infection and is associated with a 25% to 35% chance of infection in the newborn.[2] The survey was conducted as part of the Centers for Disease Control HIV-1 Family of Surveys.[3-5] In this report, we summarize HIV-1 infection levels in childbearing women classified by area of residence, race/ethnicity, and age. The present survey also provides relatively unbiased evidence on the extent of vertically acquired pediatric HIV-1 infection in California.

Methods

The study population consisted of all California women delivering live babies between July 1 and September 30, 1988, and screened for genetic diseases by the California Department of Health Services (CDHS) (accounting for approximately 99.8% of live births). A total of 136 861 births were eligible after excluding nonresidents and redundant records from multiple births.

The survey used newborn blood specimens and maternal demographic information, stripped of identifiers, originally collected for the CDHS Newborn Screening Program (NSP). HIV-1 antibody in newborn blood is maternal anti-HIV-1 IgG and indicates infection in the mother.[6] Following procedures for HIV-1 antibody detection in dried blood,[6,7] specimens were tested by enzyme immunoassay (EIA) and Western blot at the CHDS Viral and Rickettsial Disease Laboratory in Berkeley. Repeatedly EIA-reactive specimens with Western blot bands present at any two of p24, gp41, or gp120/160 were interpreted as positive.[8]

Analyses treated study subjects as a sample of childbearing women, representative of those recently giving birth; numbers of confirmed HIV-1 positive specimens were assumed to be distributed as binomial random variables. Multiple logistic regression analyses examined associations between HIV-1 antibody status and maternal race/ethnicity, region of residence, and age group.

Results

Nearly half of eligible births were delivered to San Francisco Bay Area and Los Angeles residents, with the remainder (50.8%) delivered to residents of "other California areas" (see Table 1). Although maternal age was missing for many NSP records, the survey distribution of known ages closely matched the maternal age distribution from 1988 California birth certificates.[9] For race/ethnicity, however, comparison with birth certificates suggested higher rates of missing data for both Black and White women in the survey.

Blood samples were tested for 135 808 births, or 99.2% of those eligible for the survey; specimens for 1053 births were missing or inadequate. Antibody to HIV-1 was confirmed in 101 specimens; 7 specimens with indeterminate Western blots (five p24 only, two p55 only) were interpreted as negative. Thus, there is an

Unknown	42 840	45	0.105	(.078–.142%)	2.85	(1.65–4.93)
Total sample	135 808	101	0.074	(.061–.091%)		

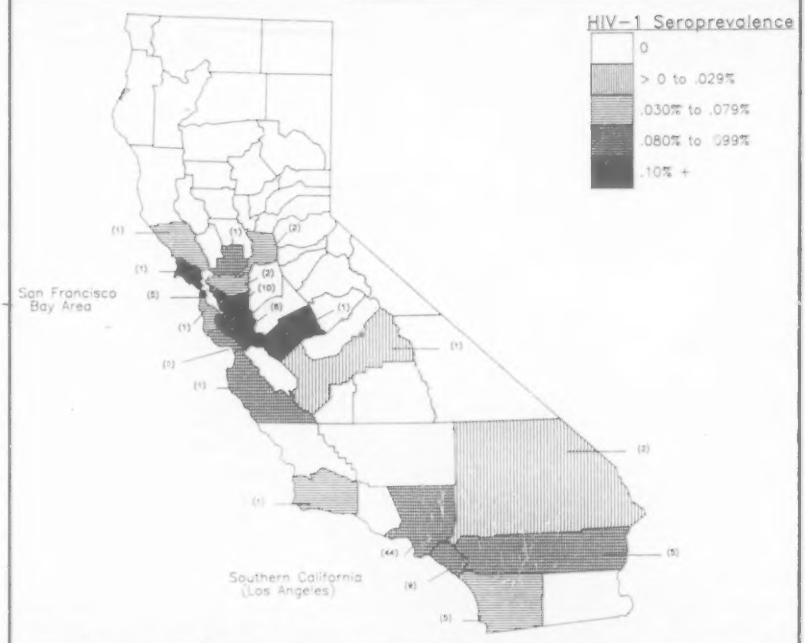
Note. CI = confidence interval.
[a]Includes Alameda, Contra Costa, Marin, San Francisco, San Mateo, and Santa Clara counties.
[b]Reference category for odds ratio calculation.

overall prevalence of infection of 0.074%, or 7.4 per 10 000 live births during the study period. Seroprevalence was lowest among women in the other California area (4.4 per 10 000). Los Angeles childbearing women were more than twice as likely to be infected as those from the other California area. San Francisco Bay Area women had the highest region-specific rate of HIV-1 infection, nearly three times that for other California women.

To provide additional geographic detail, Figure 1 displays rates and numbers of seropositive women for individual California counties. During the study period, one or more HIV-1 seropositive women gave birth in 19 of the state's 58 counties. Although the clustering of infection around San Francisco and Los Angeles suggests limited geographic spread, these 19 counties make up 86% of California's population.

Relatively low rates of infection were observed for Asian and White women in the survey (3.5 and 3.0 per 10 000, respectively). However, Hispanic women in the survey had just over twice the level of infection seen in White women, and Black women had the highest rate of infection: 36.3 per 10 000. In other words, 1 in 275 Black women delivering live babies during the study period was infected with HIV-1. This is over 12 times the rate for White women in the study. Seroprevalence among women with race/ethnicity coded as "other/unknown" was similar to that among the total sample.

Age-specific HIV-1 infection rates were lower among women under 25 years and those over 34 years in comparison with survey participants aged 25 to 34. These differences should be interpreted cautiously because age was more often missing among HIV-1-positive women. (Age was unknown in 45% of HIV-1-infected women vs 31.5% of women overall.)



Shaded areas indicate ranges of county-specific HIV-1 seroprevalence rates. Shown in parentheses is the number of HIV-1 seropositive childbearing women for each county with an infection rate greater than zero.

FIGURE 1—Geographic distribution of HIV-1 seroprevalence in California childbearing women, by county of residence: third quarter 1988.

In logistic regression analyses, both the elevated infection levels for Hispanic and Black women (relative to those for White and Asian women) and the differences among maternal age groups seen in Table 1 persisted after adjustment for possible confounding. With respect to re-

gional differences, only residence in the San Francisco Bay Area was independently associated with additional risk of infection. Interactive effects (e.g., being *both* Black *and* a San Francisco Bay Area resident) did not contribute to observed group differences in HIV-1 infection.

Discussion

As noted, HIV-1 infection was confirmed in 7.4 per 10 000 California childbearing women; this is in the same range as California female military applicants[10] and childbearing women in Texas,[5] but it is lower than findings on similar surveys in the eastern United States.[5,6,11] Preliminary results from a 1989 survey of California births indicate that, as in other states, overall seroprevalence has remained relatively stable. Within California, HIV-1 seroprevalence was highest among San Francisco Bay Area women; other regional variation appeared to reflect geographic differences in population demographic composition. AIDS cases had previously been reported in all counties where births to seropositive women occurred; one county, however, had no previous IDU or heterosexual contact cases in females, and three had no previous cases of "parent-at-risk" mode pediatric AIDS.[1]

More than a third of the estimated 400 HIV-1-infected California women delivering live babies annually are Black, and nearly another third are Hispanic. In contrast, whereas 32% of California female IDU and heterosexual contact AIDS cases are Black, only 15% are Hispanic. The proportion of Hispanic women among prevalent seropositives suggests that their representation among new female AIDS cases in the state is likely to increase, perhaps as much as twofold.[12]

This survey cannot address how sociodemographic differences in infection rates relate to patterns of risk behavior.[13] Although IDU and heterosexual contact each account for roughly equal numbers of female AIDS cases in California, the odds that a Black female AIDS case became infected through IDU (vs heterosexual contact) are three times greater than those for a Hispanic female case.[14] Such differences may reflect differing drug use or sexual mixing patterns, earlier introduction of HIV-1 into certain ethnic communities, or culturally linked differences in ascertaining transmission mode on AIDS case reports.

Over half a million children (532 708) were born in California during calendar year 1988;[9] assuming 25% to 35% vertical transmission efficiency,[2] the present survey suggests that roughly 120 of these infants were HIV-1 infected. This exceeds the cumulative number of "parent-at-risk" pediatric AIDS cases reported to date in California.[1]

Unlinked serosurveys in childbearing women may provide the best available information on the status of the HIV-1 epidemic among sexually active women in the United States. Increasingly, these surveys are being used to estimate HIV-1 infection rates or to model AIDS incidence in other population groups,[5,15] thus underscoring the need for careful assessments of survey bias.[16] The present survey covered 99.8% of live births during the study period, with HIV-1 serostatus determined for 99.2% of these. Demographic data were missing for many in the survey and, especially for maternal age, appeared less completely ascertained for women with higher rates of infection. Risk of HIV-1 infection may differ for eligible women excluded from the survey as well as for those who do not become pregnant or whose pregnancies do not end in live births. Additional data from population-based surveys of risk behavior and reproductive history and from HIV-1 serosurveys in other groups of women are needed to establish the limits of generalizability of information from surveys in childbearing women. □

Acknowledgments

This work was supported through Cooperative Agreement U62/CCU90219 between the California Department of Health Services (CDHS) and the Centers for Disease Control. The authors gratefully acknowledge the valuable contributions of Cynthia Cossen and Shirley Hagens of the CDHS Viral and Rickettsial Disease Laboratory; Daniel Morales and Terry Kennedy of the CDHS Clinical Chemistry Laboratory; and Erica Gordon, Karen Kan, and Wayne Nelson of the CDHS Genetic Disease Branch. Jim Singleton of the CDHS Office of AIDS provided statistical consultation. Erica Gordon, Richard Emmons, Jim Singleton, and Mary Jess Wilson provided useful comments on earlier drafts of the manuscript.

Cesarean Section Rates in Italy by Hospital Payment Mode: An Analysis Based on Birth Certificates

Roberto Bertollini, MD, MPH, Domenico DiLallo, MD, Teresa Spadea, PhD, and Carlo Perucci, MD

ABSTRACT

This study, based on birth certificate data from 1985 through 1987, investigated cesarean section (CS) rates in the Lazio region of Italy and their relationship with mode of hospital care payment. Use of abdominal delivery increased from 22.3% in 1985 to 24.3% in 1987. CS rates were highest (34.7%) in private hospitals. A marked variation in the use of CS was associated with mode of hospital care payment independently from other predictors of abdominal delivery. (*Am J Public Health.* 1992;82:257–261)

Introduction

Cesarean section (CS) deliveries have consistently increased in the past decades in Europe, North America, and the Pacific.[1] In the United States one out of four deliveries took place by CS in 1988,[2] and CS is the most common surgical procedure.[3] High CS rates are also observed in developing countries such as Brazil[4] and Puerto Rico.[5]

Several explanations and hypotheses have been offered to explain this impressive change in medical practice, such as a policy of subsequent cesarean delivery after a first cesarean, reluctance to deliver breech babies vaginally, and fear of malpractice suit.[6]

The use of CS for delivery is associated with nonclinical factors: socioeconomic status of women,[7] physician practice style,[8,9] physician work schedule,[10] and private or clinic care.[11] It has been shown in the United States that source of payment for obstetrical care is strongly associated with CS use, with women privately insured having the highest CS rate.[12] This observation was not confirmed in other countries with different health care systems.

In a previous preliminary report focusing on 1985 data regarding the Lazio region of Italy, we observed a high overall frequency of CS (22.5%) and a higher rate in private maternities (32.3%), where women pay all expenses for delivery.[13] To confirm this preliminary finding and investigate CS time trends, we analyzed birth certificate data for single infants born in 1985 through 1987 to women resident in the Lazio region. We compared the rates of CS by hospital payment mode after controlling, with logistic regression analysis, for the potential confounding effects of age, parity, birth weight, gestational age, presentation at birth, and day of delivery.

Materials and Methods

The study was based on an analysis of the birth certificates of single infants (live or stillborn) weighing more than 500 g and born to women resident in Lazio, a large region of central Italy, in the years 1985 through 1987. The largest city of the region is Rome, and the total regional population is about 5 100 000. Birth certificates are collected by the Medical Birth Registry coordinated by the Epidemiology Unit of the Regional Health Authority. Data on births are routinely linked to death certificates regarding deaths in the first year of life. The characteristics of the registry and the validation of data are described elsewhere.[14]

Hospital of birth was classified according to mode of medical care payment. There are three types of maternities in the Italian National Health Service (NHS): (1) NHS public hospitals, where medical care is provided free of any charge; (2) NHS private hospitals, where NHS pays a portion of the expenses (e.g., daily fees and medication) and the patient is responsible for physician fees and special services (e.g., individual room); and (3) private hospitals, where patients pay all expenses and no support is provided by NHS.

There are 96 maternities in the region (56 NHS public hospitals, 26 NHS private hospitals, and 14 private hospitals), with a total of about 47 000 births per year. All private hospitals are small units with a low number of births (e.g., the mean in 1986 was 191 births per year). Only 5 hospitals have more than 1500 births per year; 2 are teaching hospitals.

The initial cohort considered for the present study consisted of 139 284 single births; 2618 subjects were excluded (90 home births and 2528 with unknown information on mode of delivery and/or hospital of birth). The final cohort studied included 136 666 single hospital births. CS

rates were obtained by dividing the number of caesareans by the appropriate number of births (per 100).

Consistent with past research,[15–17] variables potentially predictive of CS were considered: maternal age, parity, gestational age, birth weight, presentation at birth, and day of the week of birth (weekday vs Sunday). The latter variable was considered because it had been associated with CS frequency in a previous analysis.[18] The Italian birth certificate does not include information on complications of pregnancy such as previous CS, dystocia, and fetal distress.

The strength of the association between CS rate, hospital payment, and the other predictive variables was evaluated using the odds ratio (OR); 95% confidence intervals (CIs) of the ORs were obtained using the test-based method.[19] Time trends were evaluated using the extended Mantel-Haenszel test.[20]

To assess the constancy of the relationship between payment source and CS rates, the data were stratified by maternal age, parity, birth weight, gestational age, presentation at birth, and day of delivery and the adjusted ORs calculated according to the Mantel-Haenszel method.[21] To further validate the findings derived from the above method, logistic regression analysis was employed to simultaneously estimate the independent effect of payment mode adjusted for the other predictive variables. The results of the multivariate analysis closely agreed with those of the tabular one. No statistical criteria (such as the stepwise procedure) were employed to select variables to be included in the model. Tests of significance for model selection depend on the size of the studied population, and, in large studies such as the present one, any trivial variable may have a highly significant association with the event under study (small P values) regardless of its epidemiological and clinical meaning.[22] Adjusted ORs and 95% CIs were derived from the estimated regression coefficient.[23] An interaction term (parity by maternal age) was included in the equation to take into account the joint effect of these two variables.

Results

The overall rate of CS in the years 1985 through 1987 among the 136 666 women delivering single infants in Lazio was 23.1% (Table 1). A marked statistically significant time trend ($P < .0001$) was observed over the time period studied (from 22.3% in 1985 to 24.3% in 1987). Provisional data for 1988 indicated a rate of 25.2% (R.B., unpublished data, 1991). Operative deliveries (forceps plus vacuum) constituted 2.8% of total deliveries without significant time trends.

A strong relationship was found between mode of hospital payment and CS rate. Women delivering in private hospitals had the highest CS rate (34.7%), while the rate of abdominal deliveries was lowest in NHS public hospitals (21.3%) (Table 2).

Maternal Age

The CS rate increased with maternal age: rates ranged from 16.4% among women younger than 20 years to 43.8% among those older than 39, an OR of 3.97 (95% CI = 3.54, 4.45). The rate was 18.2% among women 20 through 24, 21.7% among women 25 through 29, 26.4% among women 30 through 34, and 33.9% among women 35 through 39.

CS rates in private hospitals were significantly higher than those in NHS private and public hospitals in all age classes, except among the younger women (Figure 1). In the latter group, women delivering in NHS private institutions experienced the highest CS rate (18.3% vs 14.7% in NHS public and 16.6% in private hospitals); the difference among the three types of hospitals was of borderline statistical significance ($P = .055$). The CS rate among women older than 39 was extremely high in the private hospitals (51.1%).

Parity

The rate of CS significantly decreased with parity (23.9% for parity 0 and 22.4% for parity higher than 0). Within each parity class, the highest CS rate was observed in private hospitals (Figure 2). Since delivering in private hospitals can be judged as a proxy of the socioeconomic status of women,[18] and considering that most affluent women tend to be of lower parity and older maternal age,[7] the ORs of CS rates by hospital type were adjusted by maternal age and parity distribution. The adjusted OR_{mh} of CS in private hospitals was 1.58 (95% CI = 1.50, 1.66), as compared with 1.96 in the crude analysis; no important change was observed for NHS private hospitals ($OR_{mh} = 1.32$ vs $OR_{crude} = 1.34$).

Birth Weight and Gestational Age

The rates of CS were highest among women who delivered low-birth-weight (LBW) infants (34.3%), decreased with increasing birth weight (22.5%), and slightly increased for large babies (23.6%) (Table 3).

For each birth-weight class, CS rates significantly increased in going from NHS hospitals to the other two categories ($P < .0001$), although in private units a lower proportion of LBW and large babies at higher risk of CS were reported.

CS rates among women who delivered prematurely were highest (30.0%), decreased for full-term pregnancies, and increased again for postmature babies (24.5%) (Table 4). Again, rates were con-

sistently and significantly higher ($P < .0001$) in private units at any gestational age.

Complications

The use of CS is associated with various complications of pregnancy that are indications for carrying out the procedure.[24] The only complication reported in the Italian birth certificate is breech presentation of fetus at labor. The overall frequency of this complication was 3.3% and did not vary by hospital type. The rates of CS were highest in private and NHS private hospitals (84.7%), as compared with NHS public hospitals (75.7%) ($P < .001$).

Day of Delivery

CS rates were consistently lower on Sundays in all types of hospitals (overall CS rate of 15.7%), as compared with weekdays (overall rate of 24.1%). There was a statistically significant trend with regard to frequency of deliveries on Sundays ($P < .0001$): The lowest rate was observed in private hospitals (8.8%), the highest in NHS public units (12.2%), and an intermediate value in NHS private maternities (10%).

Multivariate Analysis

The results of the simultaneous multiple logistic adjustment are shown in Table 5. The ORs referring to maternal age and parity are shown for each combination of these two variables. Compared with the univariate analysis of unadjusted ORs, the multivariate assessment indicated that hospital payment mode was still associated with the likelihood of CS when allowance was made for the effects of the other variables present in the model. However, the OR associated with private hospitals was lower than the one observed in the crude analysis. This could be attributed to the maternal age–parity effect discussed previously, in part counterbalanced by the combined effect of the other variables in the model. The CS OR associated with NHS private maternities was practically identical to the one observed in the crude analysis.

The effect of maternal age on CS rate was marked for older/parity 0 women as compared with younger women and women of the same age at parity higher than 0.

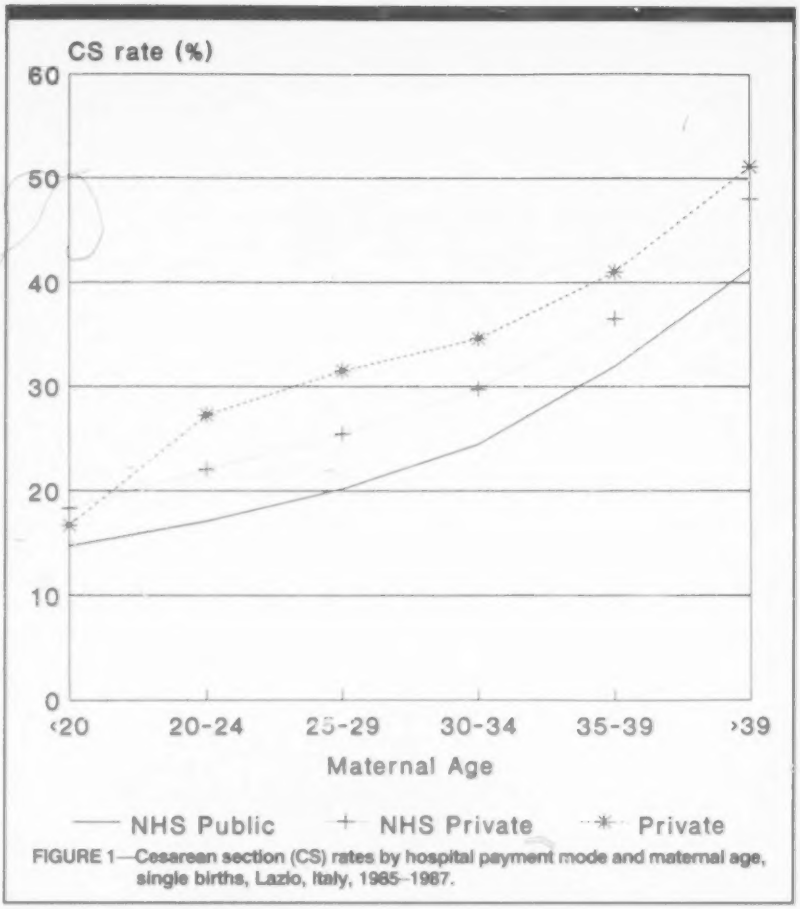

FIGURE 1—Cesarean section (CS) rates by hospital payment mode and maternal age, single births, Lazio, Italy, 1985–1987.

Discussion

This study showed that in the Lazio region of Italy, approximately one of four babies was born by CS in the time period 1985 through 1987, the highest rate reported in Europe so far. Lazio figures were comparable to those observed in the United States in the same time period,[25] and were largely beyond the figure considered acceptable by international agencies.[26] The proportion of operative deliveries (forceps and vacuum) was minimal and did not follow any time trend.

Mode of payment for obstetric care was strongly associated with CS rates after controlling for the effects of the other available determinants of abdominal delivery. Because of the limited information included in the Italian birth certificate, the effect of some known determinants of CS could not be taken into account, namely previous CS delivery, dystocia, and fetal distress. However, it is unlikely that these variables were differently distributed in the three types of hospitals to such an extent as to modify the observed effect of mode of payment on CS rates. In fact, the heterogeneous CS rates by payment mode were also observed in primiparous women (Figure 2). On the other hand, data referring to breech deliveries, the only complication of pregnancy reported in the birth certificate, confirmed higher CS rates in NHS private and private maternities than in NHS public hospitals.

The heterogeneity of CS rates by hospital payment mode might be attributable to the interaction of a variety of factors, including characteristics of patients, mix of physicians, and organizational features. In the Lazio region, delivering in private maternities can be judged as a proxy of high socioeconomic status,[18] which is associated with higher CS rates.[7] In addition, a multiplicity of financial incentives, such as a higher physician fee for CS as compared with vaginal delivery and congruence of physician interest with that of hospital (long hospital stay after CS), may influence directly or indirectly the clinical decision.[27] It is interesting to note that, in Italy, most obstetricians work part-time in both public hospitals and private institutions (NHS private or private), making the two health care settings fully comparable with regard to physician training and age. This suggests that different decision-making rules were applied to different health-

care settings for comparable clinical situations and comparable availability of diagnostic and surgical facilities. These different rules might be associated with the following factors: scheduling practices (such as 24-hour coverage by a staff obstetrician) that diminish the incentives for "convenience" CS in public maternities,[10] social congruity between obstetricians and middle-class parturients associated with the attitudes of these women toward the potential benefits of medical technology,[7] and the stronger fear of malpractice suits in cases of complication of pregnancy when caring for affluent and

more educated women, although malpractice suits in obstetrics are not common in Italy. All these elements may interact with physician practice style, which is associated with variability of CS use.[8] The decision to undertake a CS section is, in fact, not guided by unequivocal criteria; on the contrary, it is associated with a marked interobserver and, more surprising, intraobserver variability.[28]

In summary, our analysis of birth certificate data showed that the CS rate in 1985 through 1987 in the Lazio region was one of the highest ever reported. No tendency toward a leveling off of the rate, as observed in other countries,[2,5] was detected. This finding, together with the association of CS rate and hospital payment mode, was of great concern and underlines the urgent need for adopting regional and national strategies to reduce the use of abdominal delivery to more acceptable levels. □

Professional Relationships between Midwives and Physicians: Collaboration or Conflict?

Laura-Mae Baldwin, MD, MPH, Heidi L. Hutchinson, MD, and Roger A. Rosenblatt, MD, MPH

ABSTRACT

This study examines the professional relationships between midwives and physicians providing obstetrical care in Washington State. Four hundred ninety-six randomly sampled family physicians and obstetrician-gynecologists and 211 certified nurse, licensed, and lay midwives were surveyed to learn more about midwife/physician consulting relationships. Only certified nurse midwives have forged mutually satisfactory relationships with the physician community. Increased hospital-based training and practice opportunities are needed before licensed midwives can improve their professional relationships with physicians. (*Am J Public Health.* 1992;82:262–264)

Introduction

Midwives have become increasingly important birth attendants in Washington State, particularly as many family physicians and obstetricians have discontinued their obstetrical practices because of malpractice liability concerns.[1] The proportion of births attended by licensed and certified nurse midwives increased more than fortyfold between 1975 and 1989, from less than 1% to 4.6% of all births (P. Starzyk, personal communication, May 1991).[2] In 1989, 3436 Washington birth records listed a midwife as the attendant. Since 1988, six clinics, each designed to serve over 300 low-income pregnant women per year, have been established in Washington using certified nurse midwives as providers. One barrier to the further growth of midwifery has been the development of functional, mutually satisfying professional relationships between midwives and physicians. We surveyed Washington's obstetricians, family physicians, and midwives to better understand the nature of their professional relationships.

Methods

We identified 64 certified nurse midwives and 68 licensed midwives registered with Washington's Department of Licensing in 1987, as well as 79 lay midwives—66 identified by a Christian lay midwifery organization and 13 by the Department of Licensing. Because lay midwives are not licensed, our sample may not be truly representative of this group. Certified nurse midwives are registered nurses with advanced training in midwifery in a program accredited by the American College of Nurse-Midwives.[3] Licensed midwives consist mainly of graduates of the Seattle Midwifery School, a 27-month program for students who have completed at least 2 years of college.[4] Washington is unusual in having a large group of professional, nonnurse midwives who are recognized and licensed by the state. Lay midwives are allowed to practice in Washington State without any specific educational requirements but cannot advertise or charge for their services.[2] We also identified 496 family physicians and obstetrician-gynecologists randomly sampled from the 1988 American Medical Association directory's listing of Washington physicians.[5]

To describe the geographic distribution of midwives and physicians, we aggregated Washington's 39 counties into 4 categories. Urban counties are those with 76% to 100% of the population living in an urban area, semiurban 51% to 75%, semirural 25% to 50%, and rural 0% to 25%. In Washington State, 4 counties are classified as urban, 15 as semiurban, 8 as semirural, and 12 as rural.

Two survey mailings were sent to midwives and physicians in the summer of 1988 asking questions regarding physician/midwife demographics, practice characteristics, and consultation and referral relationships. After excluding those providers who had retired, died, or recorded a different specialty, 51% of physicians (234/458), 66% of certified nurse midwives (42/64), 71% of licensed midwives (48/68), and 42% of lay midwives (33/78) responded to the questionnaire.

Results

Ninety percent of obstetricians (45/50), 37% of family physicians (66/180), 69% of certified nurse midwives (29/42), 71% of licensed midwives (34/48), and 48% of lay midwives (16/33) were providing some component of obstetrical care in 1988. Nearly all practicing midwives provided prenatal care, but certified nurse

TABLE 1—Practice Characteristics of Obstetrical Care Providers

	Physicians		Midwives		
	Obstetricians (n = 45)	Family physicians (n = 66)	Certified nurse (n = 29)	Licensed (n = 34)	Lay (n = 16)
Average no. of deliveries in 1987	142	39	83	38	15
Average years in practice	13	12	8	7	7
Private practice, %	80	79	31	97	99

TABLE 2—Practice Location of Obstetrical Care Providers

	Physicians		Midwives		
Practice location, %	Obstetricians (n = 45)	Family physicians (n = 66)	Certified nurse (n = 29)	Licensed (n = 34)	Lay (n = 16)
Urban	62	51	69	54	7
Semiurban	27	29	19	27	65
Semirural	11	11	4	19	14
Rural	0	9	8	0	14

midwives (86%) and lay midwives (81%) attended deliveries to a lesser extent than licensed midwives (97%). Obstetricians and certified nurse midwives attended the greatest number of deliveries (Table 1). Most physicians and midwives practiced in urban and semiurban counties (Table 2), while few lay midwives practiced in urban counties.

Certified nurse midwives (69%) worked primarily as employees of hospitals or physicians, while licensed and lay midwives were almost exclusively in private practice. Certified nurse midwives attended the majority of their deliveries in birthing centers or hospitals (76%), while licensed and lay midwives attended deliveries almost exclusively in the home (91% and 99%, respectively).

Nearly 67% of obstetricians and 44% of family physicians had consulted for or received a referral from a midwife at some point in their medical practice. Fifty-six percent of obstetricians and 32% of family physicians practicing obstetrics had an existing referral relationship with a midwife in 1987. Of those who had not worked with a midwife, 50% of obstetricians and 51% of family physicians stated that they would be willing to do so. Seventy-six percent of all physicians practicing obstetrics felt that midwives can provide an acceptable alternative to physician care for low-risk pregnancies. No physician was willing to attend a home delivery, however.

Of the practicing midwives, 100% of certified nurse midwives (29), 97% of licensed midwives (33), and 50% of lay midwives (8) had an existing referral relationship with a physician. Certified nurse midwives predominantly consulted with and referred to obstetricians, while licensed and lay midwives had referral relationships with both obstetricians and family physicians (Table 3). Referral relationships for certified nurse midwives generally were established by their place of employment or the consulting physician (83%), while licensed and lay midwives usually approached physicians directly. Sixty-two percent of certified nurse midwives had a written contract; 52% met regularly with a physician to maintain their professional relationships.

TABLE 3—Midwife/Physician Relationships

	Certified Nurse Midwives (n = 29)	Licensed Midwives (n = 33)	Lay Midwives (n = 8)
Referral relationship with, %:			
Obstetrician	89	66	38
Family physician	11	34	38
Naturopath	0	0	25
Midwife-initiated relationship, %	17	88	88
Length of relationship, y	5	4	3
Written contract with physician, %	62	6	0
Regularly scheduled meetings/contact with physician, %	52	0	13
Average miles to physician practice	5	8	23

Sixty-nine percent of certified nurse midwives felt that no changes were needed in their referral relationships. Virtually all licensed midwives, however, wanted to establish more formal referral relationships with physicians. Midwives sought increased respect, appreciation, and communication from their physician colleagues. They also wanted greater integration with the traditional medical system through support for hospital privileges, more physicians willing to provide backup, and insurance coverage for home deliveries.

Discussion

Midwives are not a homogeneous group. Certified nurse midwives are closely aligned with traditional obstetrical services. They perform large volumes of deliveries, usually within hospitals in urban and semiurban counties. Lay midwives are most distant from the established medical community. Those we were able to contact either had no professional relationship or had informal, short-term relationships with physicians. Licensed midwives occupy an uncomfortable middle ground. They deliver almost exclusively in the home, yet rely on physicians—who, as a rule, refuse

to perform or assist in home deliveries—for consultation and referral. This group has developed less formal and less satisfying relationships with physicians than have certified nurse midwives.

Certified nurse midwives have developed a role in the institutionally based obstetrical care system, through which they are helping address problems of access for economically disadvantaged populations in Washington. Licensed and lay midwives have practiced primarily outside the mainstream of medicine. Without formal training and licensing, lay midwives will continue to practice in this manner. Licensed midwives, despite their status as licensed birth attendants, have been dissatisfied with their consulting relationships with physicians. Hospital-based training and practice opportunities must be developed if licensed midwives are to play a more significant role in providing obstetric care in Washington State. □

Factors Associated with Artificial Feeding in Shanghai

Yue Chen, MD, PhD

ABSTRACT

Factors associated with artificial feeding were analyzed for 3285 infants in Shanghai. Boys, those from more highly educated families, and those born by assisted delivery or by cesarean section were more likely to be artificially fed than were girls, those from less educated families, and those born by spontaneous delivery. Infants whose birth weight was around 3750 g had the lowest probability of artificial feeding; higher and lower birth weights were positively associated with artificial feeding. (*Am J Public Health.* 1992;82:264–266)

Introduction

Artificial feeding has been documented as an important risk factor in increased mortality and morbidity from respiratory illness, gastroenteritis, and otitis.[1–4] In China, pneumonia and diarrhea are the most common diseases in infants and children.[5] Because breast-feeding makes a unique, fundamental contribution to the health of infants, the reasons for unsuccessful breast-feeding are important concerns.[6,7]

Factors found to be related to artificial feeding have been diverse and inconsistent. The amount of information available for some geographic areas is sparse; in particular, very little information is available for China, the world's most populous country.

In Shanghai, one third of the mothers studied did not initiate breast-feeding.[3,4] The proportion of artificial feeding was surprisingly high compared with the findings from other developing countries or even some developed countries.[6–8] This paper presents information on some factors associated with the infant-feeding practices of mothers in Shanghai.

Methods

This analysis was performed on the combined data from the Jing-An and Chang-Ning epidemiological studies of children's health in Shanghai.[9,10] A detailed description of the populations and methodology has been published elsewhere.[9,10] All together, the data of 3285 infants from these two studies were used in this analysis.

The relationship between birth weight and the proportion of artificial feeding was U-shaped. Nonlinear regression[11] was used to estimate parameter values for the model

$$\text{artificial feeding} = a + b\,(\text{birth weight} - c)^2.$$

A multiple logistic regression model was used to examine the individual contribution of each risk factor to proportion of artificial feeding. The transformed values of birth weight, $(\text{birth weight} - c)^2$, were used to fit the model. All other variables were treated categorically.

Results

Table 1 shows that the proportion of artificial feeding was slightly higher in the Jing-An study than in Chang-Ning study. In Jing-An District, a higher proportion of parents had university education, the mothers were older at the time of birth, the infants were more likely to be delivered by cesarean section, and the average income per person was higher than that in Chang-Ning District. There were no significant differences between the two infant populations in sex, multiple birth, maternal history of spontaneous abortion, or average birth weight, which was 3229 g in both groups.

Of the 3285 infants, 1132 (34.5%) had never been breast-fed. As Table 2 shows, the proportion of artificial feeding was higher in boys than in girls. Artificially fed infants were likely to be from families in which the father was more highly educated than the general population. Infants who were born by assisted delivery or by cesarean section were more likely to be artificially fed than were those delivered by spontaneous labor. Multiple births had a higher proportion of artificial feeding than did the general population.

Birth weight was another important predictor of frequency of artificial feeding. The average birth weight for all infants was 3229 g (SD 441 g). The relationship estimated by nonlinear regression is shown in Figure 1 ($t = 6.453$, $P < .001$). Infants whose birth weight was 3750 g had the lowest proportion of artificial feeding (30.4%). Higher and lower birth weights were associated with higher proportions of artificial feeding.

The variables in the final logistic model included study (Jing An or Chang-Ning), sex, birth weight, type of delivery, and father's education. The adjusted odds ratios for the proportion of artificial feeding were 0.85 (95% confidence interval [CI], 0.73–0.98) for girls compared with boys and 0.76 (95% CI, 0.61–0.96) for those from families with less educated fathers compared with those from families with university-educated fathers. The adjusted odds ratios for children born by cesarean section and those born by assisted delivery were 1.45 (95% CI, 1.19–1.75) and 1.41 (95% CI, 1.14–1.74), respectively, compared with those born by spontaneous delivery.

The transformation of birth weight, $(\text{birth weight} - 3750)^2$, was used to fit the logistic model. The U-shaped relationship was slightly stronger after adjustment for the covariates.

*$.05 < P < .10$.
**$P < .01$.

The average birth weight in the multiple-birth group was significantly lower than that in the general population (2625 g vs 3242 g, $t = 11.654$, $P < .001$). After adjustment for the covariates, the effect of multiple birth is no longer statistically significant. No significant relationships were found between the proportion of artificial feeding and other factors, including maternal age at birth, mother's educational status, maternal history of spontaneous abortion, and average income per person in the family.

Discussion

The lowest proportion of artificially fed infants was found among those with birth weights of around 3750 kg. Both smaller and larger infants were more likely to be fed artificially. Previous studies have reported that lower birth weight was related to a lower proportion and shorter duration of breast feeding,[7,8] but the results from different studies are not consistent.

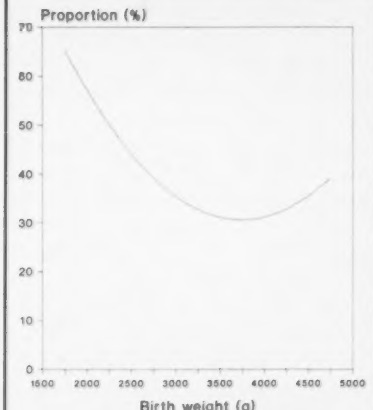

FIGURE 1—Relationship between proportion of artificial feeding (PAF) and birth weight (BWT).

The U-shaped relationship between birth weight and proportion of artificial feeding has not been described previously, possibly because in previous stud-

ies, birth weight was treated dichotomously or categorically, and infants with birth weights of 3500 g or more were all classified into same group. The biological explanation for the U-shaped relationship remains unclear. It could be that small infants have difficulty in establishing breast feeding and large infants are unable to have their need for more milk satisfied by their mothers.

Artificial feeding was more common in infants born by assisted delivery or by cesarean section than in those born by spontaneous delivery. These results are consistent with the findings reported previously.[7,8,12,13] It has also been demonstrated that assisted delivery and cesarean section were associated with delay in starting breast-feeding.[14] Poor condition of abnormally delivered infants and the separation of mother and infant have been suggested as factors responsible for the delayed initiation of breast-feeding.[12] Delayed lactation and the use of anesthetics could have long-term consequences on the establishment and duration of breast-feeding.

In this analysis, it was found that paternal education was positively associated with the proportion of artificial feeding. It seems that in Shanghai, infants in well-educated families were more likely to be fed artificially. Some previous studies have found that lower maternal educational level was associated with a higher proportion of breast-feeding.[15,16] Other studies, however, showed that higher maternal education could improve breast-feeding practice.[7,8] The association seems to be linked to a variation by country or by ethnic group within a country.

In conclusion, birth weight, type of delivery, paternal education, and sex of the infant are significant predictors of artificial feeding in Shanghai. These findings will assist the development of breast-feeding promotion programs in Shanghai. □

Smoking-Related Behavior, Beliefs, and Social Environment of Young Black Women in Subsidized Public Housing in Chicago

Clara Manfredi, PhD, Loretta Lacey, RN, DrPH, Richard Warnecke, PhD, and Marianne Buis, PhD

ABSTRACT

Survey data indicate that young Black female smokers living in public housing are heavier smokers and have weaker motivation to quit, health beliefs and social environment less conducive to cessation, and less knowledge of where to get help to quit than other young Black female smokers in metropolitan Chicago. Compared with White women, the latter, other Black women smoke fewer cigarettes daily and have a stronger desire to quit and more concern about health reasons for quitting, but have a weaker belief in the risk of lung cancer from smoking, greater concern about quitting difficulties, and less knowledge of where to get help to quit. Low education, not race, is associated with higher smoking prevalence and less social pressure to quit or support for quitting. (*Am J Public Health.* 1992;82: 267–272)

Introduction

Smoking prevalence rates among young Black women of low socioeconomic status are high[1–3] and projected to remain so on the basis of current smoking cessation trends.[4–6] Smoking cessation programs tailored to this population are needed,[3,7] but few data are available about smoking differences within the Black population that are attributable to socioeconomic factors.

Smoking cessation may be particularly difficult to achieve among individuals with several of the characteristics associated with high smoking rates (including low education, income below poverty level, unemployment, employment in service-level jobs, and unmarried status[5,7,8]) and among those living in urban communities who have been described as overwhelmed by problems of poverty, crime, and decaying environment.[9–12] Under these cumulative conditions, beliefs and social norms favoring smoking cessation are likely to be weak and not very salient.

In this paper we explore the smoking-related beliefs and social environment of such a population and compare them with those of a general population of smokers. Survey data are presented for female smokers aged 18 to 39 in three groups: (1) Black residents of Chicago subsidized public housing ("Black SPH Residents"), a population subgroup of known low socioeconomic status[13]; (2) Blacks from the general metropolitan Chicago population ("Other Blacks") who are not SPH residents; (3) Whites from the general metropolitan Chicago population ("Whites") who are not SPH residents.

Methods

Samples

As part of the evaluation of a televised smoking cessation intervention, baseline telephone interviews were conducted with a general population sample of 2398 smokers who watched the evening news at least three times per week. This was a random-digit-dialing sample of the noninstitutionalized population, 18 years of age or older, in the Chicago metropolitan area.[14] The interviews were conducted 6 months before the intervention. The sample yielded 117 Other Black females and 496 White females aged 18 to 39. The SPH sample was identified by screening a random sample of 1849 apartments in three public housing developments. Each development and its buildings were sampled with probability proportionate to its share of the three developments' total population. Of these, 19% were unoccupied, the occupants of 9% refused or were unavailable, and 58% had no smokers qualifying by sex, age, or TV viewing habits.* Face-to-face interviews were completed with 246 (96%) of the 256 eligible respondents.

Table 1 shows education level, income, and employment, marital, and single-parenthood status for the three study groups.

Hypotheses

Hypothesis #1: Because of the high smoking prevalence rates associated with low socioeconomic status, Black SPH Residents are expected to be heavier

*About 87% of the general population sample and 89% of the SPH sample who were contacted and who otherwise qualified for the study were regular viewers of the local evening news, either between 4 PM and 6:30 PM or at 10 PM.

[b]A single parent has at least one child in the household and is currently neither married nor living with a partner.

smokers and to have weaker motivation to quit smoking, fewer beliefs consistent with smoking cessation, weaker social pressure, and less social support to quit than Other Blacks.

Hypothesis #2: Because of the increasing smoking rates among young Black females in general (and regardless of the well-known smaller daily cigarette consumption among Blacks[15]), Other Blacks are expected to have weaker motivation to quit smoking, fewer beliefs consistent with smoking cessation, weaker social pressure, and less social support to quit than Whites.

Variables and Statistical Methods

We used 45 dependent variables, listed in Tables 2 and 3, to test the hypotheses above and to reflect psychosocial factors commonly appearing in the smoking cessation literature.[16–18] For each variable, differences between Black SPH Residents and Other Blacks and between Other Blacks and Whites are presented with 95% confidence intervals.

Each dependent variable in Tables 4 and 5 was regressed in simultaneous logistic regression[19] with education (a three-level category) and study group. This was done separately for the two group comparisons because (1) the patterns of differences by study groups, shown in tables 2 and 3, do not warrant treating the three groups as categories in an ordinal variable and (2) for many variables the effect of education is different or even reversed by study group. Adjusted and unadjusted odds ratios and 95% confidence intervals[20] were calculated for the group comparisons and for higher versus lower education. Results are presented only for variables for which the group comparison is significantly ($\alpha = .05$) altered by education or for which education itself has a significant effect.

Results

Regarding Hypothesis 1, on virtually every comparison shown in Tables 2 and 3 Black SPH Residents revealed characteristics unfavorable to smoking cessation, and 24 of the 45 comparisons show differences in proportions significantly different from zero ($\alpha = .05$). These bivariate relationships remain when adjusted for education. Among Black SPH Residents, increased education is significantly associated only with smoking initiation after age 17, increased recognition of risk associated with current smoking level, and awareness of sources of support for quitting (see Table 4). Higher education is negatively associated with plans to quit (not significant) and worry about getting lung cancer.

Regarding Hypothesis 2, there is much less consistency in the comparisons shown in Tables 2 and 3 between Other Blacks and Whites. Compared with Whites, Other Blacks started smoking at an older age; smoke fewer cigarettes per day; have a stronger desire to quit and perceive less effort needed to quit; are more likely to expect to get lung cancer and to be very concerned about the effect of smoking on health in general; and are more likely to consider health concerns, restrictions at work, the expense of cigarettes, and showing that they are not hooked on cigarettes as very important reasons to quit.

On the other hand, compared with Whites, Other Blacks are more likely to believe the risk of lung cancer is the same for smokers and nonsmokers, are more concerned about feeling uncomfortable around smokers and being unable to deal with stress if they quit, and are less likely to know where to get help in quitting. These relationships remain after adjusting for education. However, the adjusted odds ratios and the percentages by education level shown in Table 5 indicate that, in general, educational differences are more consistent than racial differences and that as education increases, racial differences diminish. Thus differences by race are most apparent among the least educated. Education is negatively related to age of smoking onset, amount smoked, and perceived difficulties with quitting; it is positively related to plans to quit, beliefs that smoking is related to lung cancer and that lung cancer would have serious consequences, and knowledge of where to go for help in quitting. Those with more education are also more likely to live in environments that are supportive of cessation and that have fewer smokers.

Discussion

Study Limitations

This was a mixed-mode study, with face-to-face interviews with the SPH sample and telephone interviews with the others; the questionnaires, however, were identical, and there are no indications of method effects in responses to either mode, although the telephone response rate was lower (73% vs 96%). The uniqueness of the SPH sample may limit generalizability, but this population is a growing segment in many urban areas and hence is important to study. Finally, in this study we exam-

TABLE 2—Smoking Habits, Motivation to Quit, Health Belief Model Variables,[16–18] Smoking Prevalence, Social Norms and Social Support for Quitting, and Knowledge of Help Available by Three Study groups

	Black SPH Residents, % (n = 246)	Other Blacks, % (n = 117)	Whites, % (n = 496)	% Difference (95% CI)	
				Black SPH Residents vs Other Blacks	Other Blacks vs Whites
Smoking habits					
Started to smoke at age 17 or younger	68	46	56	22 (10, 34)	−10 (−21, 1)
Smoke more than 10 cigarettes per day	51	35	70	16 (4, 27)	−35 (−45, 25)
Mean no. cigarettes per day (SD)	15.6 (11.8)	12.2 (8.9)	18.5 (10.8)	3.4 (2.3, 4.5)	−6.34 (−8.4, −4.2)
Smoke menthol cigarettes	96	85	49	11 (5, 17)	36 (26, 46)
Motivation to quit smoking					
Ever tried to quit	56	66	67	−10 (−21, 1)	−1 (−10, 8)
Have desire to quit					
None or weak	54	32	35	22 (7, 29)	−3 (−13, 6)
Moderate	27	40	48	−13 (−24, −2)	−8 (−18, 3)
Strong	18	28	17	−10 (−20, 0)	11 (1, 20)
Plan to ever quit	72	90	88	−18 (−26, 9)	2 (−6, 7)
Plan to quit within 12 months	33	58	54	−15 (−36, −14)	4 (−5, 14)
Health Belief Model variables ("Agree" or "strongly agree" with each of the following statements)					
Perceived severity					
These days, there is a good chance that a person who is diagnosed as having lung cancer can be cured.	47	51	43	−4 (−15, 7)	8 (−2, 18)
If I were to get lung cancer, my whole life would change.	79	78	88	1 (−8, 10)	−10 (−17, −3)
If I were to get lung cancer, it would place a great burden on my family or friends.	81	80	87	1 (−8, 10)	−7 (−14, 3)
Perceived susceptibility					
I do not expect to get lung cancer during my life.	41	33	48	8 (−1, 15)	15 (5, 25)
My chances of avoiding lung cancer are better than other people my age.	31	16	21	15 (5, 25)	−5 (−13, 3)
A person has to smoke a lot more than I do to have a serious risk of getting lung cancer.	35	21	17	14 (4, 24)	4 (−14, 12)
Perceived risk					
The chances of getting lung cancer are the same whether or not you smoke.	57	46	27	11 (1, 21)	18 (9, 27)
Concern with risk					
I worry about getting lung cancer more than other people.	30	39	39	−9 (−20, 2)	0
I seldom worry about getting lung cancer.	61	63	60	−2 (−13, 9)	3 (−7, 13)
(The following variables were determined by respondents' answers to questions)					
Benefits of quitting					
Perceive a decrease in likelihood of getting lung cancer after quitting smoking[a]	54	55	60	1 (−4, 3)	−5 (−8, 4)
Other health concerns					
Very concerned about the effects of smoking cigarettes on health	41	46	38	−5 (−17, 6)	8 (−3, 8)
Cost of quitting					
"Very concerned" with the following problems one may experience if quitting:[b]					
Having withdrawal symptoms	39	43	30	−4 (−15, 7)	13 (4, 22)
Feeling uncomfortable around people who smoke	30	23	16	7 (−3, 17)	7 (−2, 16)

TABLE 2—Continued

	Black SPH Residents, % (n = 246)	Other Blacks, % (n = 117)	Whites, % (n = 496)	% Difference (95% CI): Black SPH Residents vs Other Blacks	% Difference (95% CI): Other Blacks vs Whites
Being unable to deal with stress	35	24	22	11 (1, 21)	2 (−6, 10)
Gaining weight	44	57	54	−13 (−24, −2)	3 (−7, 13)
Perceive effort needed to stop smoking above 5 on a 10-point scale	53	39	58	14 (3, 26)	−19 (−30, −9)
Smoking prevalence					
Most or all relatives smoke	41	37	31	4 (−7, 15)	6 (−3, 15)
Most or all friends smoke	61	46	40	15 (5, 25)	6 (−3, 15)
Social norm for quitting					
People closest to you want you to quit					
Very much	29	57	54	−28 (−39, −16)	3 (−7, 14)
Somewhat	31	22	24	9 (−1, 19)	−2 (−11, 7)
Very little or not at all	40	20	22	20 (7, 30)	−2 (−11, 7)
Expected support for quitting					
Could expect support from					
Smokers in household	43	47	52	−4 (−15, 7)	−5 (−15, 5)
Nonsmokers in household	72	80	73	−8 (−18, 2)	7 (−2, 16)
Relatives living outside household who smoke	56	80	74	−24 (−35, −13)	6 (−3, 15)
Relatives living outside household who do not smoke	69	89	89	−20 (−32, −10)	0
Friends who smoke	52	73	83	−21 (−32, −10)	−10 (−18, −2)
Friends who do not smoke	73	86	91	−13 (−22, −4)	−5 (−11, 1)
Would know where to get help to quit if needed	38	47	71	−9 (−16, −1)	−24 (−34, −14)

Note. SPH = subsidized public housing; CI = confidence interval.
[a]Perception of a decrease was determined by a positive difference between a respondent's ratings on a scale of 1 to 10 of her likelihood of getting lung cancer if she quit and if she continued to smoke.
[b]Asked only of respondents with at least a weak desire or any plans to quit (ns = 225, 110, 476).

TABLE 3—Reasons for Wanting to Quit,[a] by Three Study Groups

"Very Important"	Black SPH Residents, % (n = 179)	Other Blacks, % (n = 105)	Whites, % (n = 440)	% Difference (95% CI): Black SPH Residents vs Other Blacks	% Difference (95% CI): Other Blacks vs Whites
To help current health problems[b]	47	53	32	−6 (−18, 6)	21 (11, 31)
To avoid future health problems	70	84	74	−14 (−23, −5)	10 (2, 18)
Because of health problems of people with whom they live[b]	50	43	36	7 (−5, 19)	7 (−3, 17)
To feel better[b]	65	75	62	−10 (−21, 1)	13 (3, 23)
Because of restrictions at work[b]	6	22	9	−16 (−24, −8)	13 (6, 20)
Because of the expense of smoking	52	55	37	−3 (−15, 9)	18 (3, 28)
To show that they are not hooked on cigarettes	26	38	17	−12 (−23, −1)	21 (12, 30)

Note. SPH = subsidized public housing; CI = confidence interval.
[a]Asked only of respondents who have any desire to quit and who plan to quit someday.
[b]Cases for which question was not applicable are included as "not important" in the total n.

ined characteristics of smokers only. Different patterns might be found if former smokers and nonsmokers were also included.

Implications

Despite these limitations, the present study does have implications for smoking cessation interventions. First, the message that smoking increases the risk of lung cancer has not reached or been accepted by a large proportion of young Black female smokers with less education, although they are concerned about the effect of cigarettes on their health in general. Compared with White or better-educated females, Black females living in SPH and those with less education tend to be very concerned about their current health problems or those of people close to them, the expense of cigarettes, and being addicted to cigarettes. Smoking cessation messages may gain increased attention by emphasizing these concerns. Sec-

TABLE 4—Comparison of Black Subsidized Public Housing Residents (SPH) with Other Blacks (OB): Unadjusted and Education-Adjusted Odds Ratios for Selected Dependent Variables[a]

	Education, %						Unadjusted Odds Ratio, SPH/OB (95% CI)	Adjusted Odds Ratio[b]

[a]Omitted are dependent variables for which the comparison presented in Tables 2 and 3 is not significantly altered by education level.
[b]Adjusted using a simultaneous logistic regression model that included study group and education level.
[c]Education was treated as a covariate with three levels (low = less than high school, mid = high school, high = more than high school). The odds ratio indicates the odds for two adjacent levels (high to mid, mid to low).

ond, interventions must address the high smoking prevalence and weak norms and support for quitting in the social environment of low-socioeconomic status female smokers and the likely side effects of cessation. Third, help with cessation must be more readily available to and more heavily promoted in this population, whose members are unaware of the help available. Increased visibility of smoking cessation programs may enhance both their use and smokers' perception of the social desirability of quitting. Finally, those who target programs toward poorly educated young Black female smokers must realize that this group includes women with intensified needs and barriers—exemplified by the public housing residents who are the main focus of this study—who need special attention. □

Smoking Initiation and Cessation in Relation to Body Fat Distribution Based on Data from a Study of Swedish Women

Lauren Lissner, PhD, Calle Bengtsson, MD, Leif Lapidus, MD, Cecilia Björkelund, MD

ABSTRACT

In a representative sample of Swedish women, smokers were significantly less obese than nonsmokers. However, a smoker was likely to have significantly more upper-body fat than a nonsmoker of similar body mass index. Women who quit smoking experienced less upper-body fat deposition than would be expected by their accompanying weight gain, suggesting that weight gained as a consequence of smoking cessation is not preferentially deposited in the region associated with increased cardiovascular risk. (*Am J Public Health.* 1992;82:273–275)

Introduction

A recent survey showed that 39% of female cigarette smokers viewed smoking as a tool for weight control.[1] Weight gain and increased appetite were cited as important reasons for relapse following attempts to quit smoking. In agreement with this popular notion, epidemiological studies have demonstrated clearly that smokers weigh less than nonsmokers[2,3] and that smoking cessation leads to weight gain among both men[3–5] and women.[4–6] In two studies involving male subjects, associations have been observed between cigarette smoking and centralized body fat distribution.[7,8] Furthermore, in one of these latter studies, smoking cessation was associated with a smaller degree of upper-body fat deposition than would be anticipated from the accompanying weight gain.[7] Less is known, however, about the effects of smoking initiation and cessation on body fat distribution in women.

Thus, the aim of this paper is twofold: to describe cross-sectional associations between smoking and body fat distribution in a representative sample of Swedish women; and to examine changes in fat distribution that occur as a consequence of smoking initiation and cessation. If the findings in women are similar to those in men, this would confirm that gains in body weight following smoking cessation do not follow the androgenic fat distribution pattern associated with increased cardiovascular risk in women[9–12] and in men.[11–13]

Subjects and Methods

This analysis is based on data from the Prospective Population Study of Women in Gothenburg, Sweden. This is a representative sample of female Gothenburg residents born in 1908, 1914, 1918, 1922, and 1930. The analysis presented here uses data from the first two examinations, which took place in 1968/69 and in 1974/75. Details of the sampling, participation rates, and examination protocol have been given elsewhere.[6,9,14,15]

Anthropometric measurements were taken at the same time of day and year at both examinations. A subject's body mass index (BMI) ($weight_{kg}/height_m^2$) was used as an indicator of overall adiposity, while waist-hip ratio (waist circumference/hip circumference) reflected the distribution of her body fat, with high values indicating upper-body obesity. Changes in BMI and waist-hip ratio were calculated as 1974/75 values minus 1968/69 values. Smoking history was ascertained by means of standardized questions at each examination. Subjects who had never smoked or who had not smoked for at least a year were classified as nonsmokers. Women who reported quitting at any time during the previous 12 months were excluded.

In the cross-sectional portion of this investigation, analysis of variance was used to compare BMI and waist-hip ratio in current smokers with those in nonsmokers, using 1974/75 data. All cross-sectional findings were replicated using the 1968/69 measurements not shown. Similarly, the longitudinal analysis used data from both examinations to compare continuing smokers with women who quit smoking, and nonsmokers with women who started smoking. After controlling for age and (when appropriate) BMI, adjusted least square means were computed and reported here with their standard errors.

Results

Cross-sectional Analysis

The rate of cigarette smoking was 41.0% in 1968/69 and 37.6% in 1974/75. Smokers had lower BMIs (P = .0001) and higher waist-hip ratios (P = .003) than nonsmokers, after controlling for age, in agreement with previous findings among this cohort[6,9] (see Table 1). To determine whether smoking was associated with fat patterning independent of generalized obesity, further statistical adjustment was made for BMI. The differences between waist-hip ratios of smokers and nonsmokers were accentuated after controlling for BMI (P = .0001), indicating that a smoker is likely to have a significantly higher proportion of upper- to lower-body fat than a nonsmoker of similar body mass.

Longitudinal Analysis

Between the two examinations, 3.5% of nonsmokers started smoking and 12.7% of smokers quit. The purpose of the second analysis was to evaluate specific effects of smoking initiation and cessation on BMI and waist-hip ratio. To test for an initiation effect, comparisons were made between subjects who did not smoke at either exam and those who began smoking between the two exams. As expected, the women who started smoking tended to lose weight while the nonsmokers gained weight, and the difference between these groups was significant (P = .005). Conversely, a comparison of women who smoked at both exams with those who quit indicated that, although both groups gained weight, the quitters gained significantly more (P = .0006) (see Table 2).

To evaluate effects of smoking initiation and cessation on fat distribution, changes in waist-hip ratio were examined, with and without adjustment for changes in BMI (see Table 2). The initial analysis showed no significant effects of smoking initiation or cessation on waist-hip ratio; all four groups displayed significant increases in this ratio over time (P = .0001). However, after controlling for possible confounding by BMI changes, significant differences in the waist-hip ratio emerged in smokers versus quitters (P = .03). Waist-hip ratio increased by slightly more in smokers (+0.05) than in quitters (+0.03), which is contrary to what one would predict from their respective BMI gains of +0.5 and +1.4. It is concluded that women who stop smoking do not experience the degree of upper-body fat deposition that generally accompanies weight gain.

Discussion

International comparisons of cigarette smoking trends suggest that women are quitting less often and/or starting more often than men worldwide.[16,17] At current rates, it has been projected that the majority of smokers in the United States could be women after the year 1995.[18] Therefore, the observation that smoking cessation resulted in less upper-body fat deposition than would be expected from the concomitant weight gain may be of interest to many female smokers. Upper-body fat distribution in women is related to increased rates of coronary heart disease,[9,11] stroke,[9] diabetes,[12] and unfavorable lipid profiles,[10,12] and it may be a more potent cardiovascular risk factor than generalized obesity.[9-12] In this context, our results suggest that the weight gain that often accompanies smoking cessation need not be perceived as an adverse health effect because weight gained as a consequence of quitting smoking is not preferentially deposited in the region associated with increased cardiovascular risk. Such information, together with the similar findings in males,[7] could provide an incentive to a health-conscious public to modify smoking practices in line with a more advantageous body fat distribution, even if some overall weight gain is involved. □

Surveillance of Occupational Lead Exposure in New Jersey: 1986 to 1989

Allison Tepper, PhD

ABSTRACT

Between January 1986 and June 1989, 1916 New Jersey workers were identified through a surveillance system for occupational lead exposure. The average annual proportion of workers with a blood lead level above 2.42 μmol/L was 12%. Industries with the highest proportion of workers with blood lead levels above 2.42 μmol/L were special trade construction (35%) and industries dealing with scrap and waste materials (27%). (*Am J Public Health.* 1992;82:275–277)

Introduction

Public health agencies in several states have described surveillance programs for occupational lead exposure using biological monitoring data.[1–3] The experience in these states provides useful lessons about program design and operation for others beginning to implement lead surveillance activities. Ongoing reporting of findings helps promote the use of surveillance data for targeting and evaluating lead poisoning prevention efforts. This paper examines the results obtained by the New Jersey Department of Health (NJDOH) occupational lead exposure surveillance project between January 1986 and June 1989.

Methods

A passive surveillance system for occupational lead exposure was begun by the NJDOH in October 1985. In-state clinical laboratories are required to report test results and identifying information for adults (aged 16 and above) with blood lead levels above 1.21 μmol/L* (New Jersey Administrative Code 8:44–2.11).

The NJDOH provides educational materials to physicians and reported individuals by mail and conducts telephone interviews to ascertain the source of exposure. When a work-related exposure is

*1 μmol/L = 20.7 μg/dL.

At the time of this study, the author was with the Occupational Health Service, New Jersey Department of Health. She is now with the National Institute for Occupational Safety and Health (NIOSH), Division of Surveillance, Hazard Evaluation and Field Studies.

identified, a NJDOH representative visits the workplace or refers the matter to OSHA.

Results

Surveillance Findings

Of 2487 reported individuals, 1916 (77%) were exposed to lead in their New Jersey workplaces. The number of reports increased after the first 2 years, but there was no discernible trend in the number of new workers reported (Table 1).

The distribution of blood lead levels was consistent from year to year. On average, 27% of those reported had an annual peak blood lead level from 1.21 to 1.44 μmol/L; 43%, from 1.45 to 1.92 μmol/L; 19%, from 1.93 to 2.41 μmol/L; 7%, from 2.42 to 2.89 μmol/L; 3%, from 2.90 to 3.37 μmol/L; and 2%, above 3.38 μmol/L.

Nine facilities in four industries (cyclic crudes and intermediates, storage batteries, primary copper, and vitreous china tableware and kitchenware) accounted for 959 workers (51%) (Table 2). Forty-three facilities in 11 other industries accounted for 486 workers (26%), including 210 workers (11 percent) in metal-related industries and 143 workers (8%) in plastics-related industries. One hundred twenty-seven facilities in 77 industries accounted for the remaining 425 workers (23%), including 89 workers (5%) in the construction industry.

Blood lead levels above 2.42 μmol/L were reported for 246 workers (13%) (Table 3). Thirty-three percent of construction workers (84% of whom were special trade contractors) and 26% of wholesale trade workers (82% of whom worked in scrap and waste materials facilities) had blood lead levels above 2.42 μmol/L.

Characteristics of the Surveillance System

Ten in-state and three out-of-state laboratories provided reports to the NJDOH. Blood lead levels below 1.93 μmol/L were reported within an average of 17.9 days, compared with 19.8 days for higher levels ($P = .08$). Although laboratories nearly always provided the workers' names, blood lead levels, and test dates, most reports did not provide age (54%), address (61%), and telephone number (84%).

Discussion

The New Jersey experience demonstrates the utility of laboratory-based surveillance systems for occupational lead exposure. Positive features include clear reporting criteria, small numbers of reporting units, high specificity for detecting cases of interest, and the identification of workplaces that can be targeted for intervention. Although some high-risk industries, such as secondary smelting and battery manufacturing, are common to many states,[3] state specific, laboratory based surveillance systems identify industries important in one state but not in others, such as cyclic crudes and intermediates (which includes organic lead production) in New Jersey. Improvements are needed if these surveillance systems are to provide accurate data for assessing progress toward the Public Health Service objective of eliminating blood lead levels above 2.42 μmol/L by the year 2000.[4]

Failure to capture test results from out-of-state laboratories contributes to underestimation of the number of overexposed workers. A large increase in the number of new cases in New Jersey resulted from the initiation of voluntary reporting by an employer using an out-of-state laboratory. A California survey showed that 47% of lead-using facilities sent their specimens to out-of-state laboratories. Fifty-three percent of reports to the New York heavy metals registry were from out-of-state laboratories.[1] The feasibility of using state licensing authority to cover out-of-state laboratories (this authority is present in New York but not in New Jersey) should be considered by all states interested in lead surveillance. If possible, laboratory certification requirements of the OSHA lead standard should be modified to include provisions for reporting to states. The sensitivity of sur-

[c]Forty-six workers and 21 facilities with unknown SIC codes are excluded from the table.

veillance systems would be improved by capturing all workers with workplace biological monitoring programs, but would still be limited by the lack of monitoring in a large percentage of lead-using workplaces.[5]

The absence of complete identifying information on many reports hinders follow-up. This problem could be ameliorated by the strengthening of reporting regulations and enforcement policies. Alternate sources of information for surveillance also should be considered. For example, new reporting requirements in New Jersey allow the state to obtain information directly from physicians (New Jersey Administrative Code 8:57–3.2).

Workers in New Jersey are being exposed to lead at levels above limits in the OSHA lead standard. The proportion of New Jersey workers with the highest blood lead levels (above 2.42 μmol/L) was 12%, which is consistent with the findings from California.[2] In the absence of accurate denominator data, however, the true prevalence of overexposure among all lead-exposed workers cannot be determined. Moreover, the distribution of blood lead levels is distorted by the absence of information about blood lead levels below the reporting level.

The most severe lead exposure problems in New Jersey appear to be in the construction and scrap metal industries. In several reports of outbreaks of lead poisoning, exclusion of the construction industry from the OSHA lead standard has been recognized as a problem.[6,7] Additionally, intermittent lead exposure and a mobile work force (particularly in construction) complicate the development of adequate health and safety programs. Finally, many workers in these industries are employed in small businesses, where health and safety programs are less common.[8] In New Jersey, 92% of employers in special trade construction and 86% of employers in scrap metal industries employ fewer than 20 workers. In contrast, only 62% of employers in the manufacturing sector are in this category.[9] □

Inaccuracies in Certification of Nonmelanoma Skin Cancer Deaths

Martin A. Weinstock, MD, PhD, Hendrik A. Bogaars, MD, Michelle Ashley, MD, Virginia Litle, MD, Elise Bilodeau, MD, and Steven Kimmel, MD

ABSTRACT

Nonmelanoma skin cancer is the most common cancer site in the United States, yet mortality from this cause is poorly understood. We sought medical records of the 116 reported deaths during 1979 through 1987 from this cause (*International Classification of Diseases,* 9th version [ICD-9], code 173) among Rhode Island residents to evaluate the accuracy of the reported cause of death. Of the 110 cases for which the cause of death could be classified as correct or incorrect, 59 (54%) were misclassified, 49 (83%) of which were mucous-membrane, squamous-cell carcinomas of the head and neck. For most of these, the written death certificate diagnosis was squamous-cell carcinoma of the head and neck, which was coded 173.4. Other problematic diagnoses were cancer of the head and neck and malignant fibrous histiocytoma. In response to a mailed survey, most health departments replied that squamous-cell carcinoma of the head and neck was coded under rubric 173 and malignant fibrous histiocytoma was coded under rubric 171, but there was no unanimity. The misclassification of other causes of death to ICD-9 rubric 173 is substantial. The vast majority were coded to rubric 173.4 and were due to a small number of diagnoses that are recognizable on examination of the death certificate. (*Am J Public Health.* 1992; 82:278–281)

Introduction

Nonmelanoma skin cancer (NMSC) is by far the most commonly diagnosed malignancy in the United States and is increasing rapidly in incidence.[1–5] Mortality from this cause has been poorly studied, however. Mortality rates based on death certificate data indicate that from the 1950s to the 1970s, there was a substantial decline in death due to NMSC.[6] However, these rates may be inaccurate.[6–8] We reviewed reported NMSC deaths (a) to estimate the accuracy of death certification, (b) to evaluate secular changes in accuracy, (c) to determine the reasons for inaccuracy, (d) to assess implications for the interpretation of national NMSC mortality rate statistics, and (e) to suggest improvements.

Methods

We reviewed certificates and sought medical records for all deaths among Rhode Island residents during 1979 through 1987 for which the underlying cause of death was coded as NMSC (*International Classification of Diseases,* 9th version [ICD-9], code 173). Appendix A describes our criteria for determining whether the cause of death code was correct.

Some of the underlying causes of death written on the death certificates by the physicians certifying the deaths were potentially ambiguous with respect to appropriate ICD-9 code. To aid in distinguishing problems of coding practice from problems in coding policy, we sent a short questionnaire in September 1990 to 53 health departments (50 states, New York City, the District of Columbia, and Puerto Rico). For six diagnoses, we asked "Which ICD-9 code would you use to classify a death certificate with the following underlying cause listed on the death certificate?"

We use the term "accuracy" herein to refer to the proportion of certificates correctly classified under ICD-9 code 173 among all evaluable certificates classified under that rubric. This is the "confirmation rate,"[8] that is, the (positive) predictive value of classification under this rubric if our evaluation of the medical records is taken as the standard of reference.

P values are two-tailed and were calculated using the Student's *t* statistic or linear regression.

Results

During 1979 through 1987, 116 deaths (including 4 out-of-state deaths) among Rhode Island residents were classified under ICD-9 code 173. Six deaths were excluded (see Appendix B). Fifty-nine (54%) of the 110 remaining deaths were incorrectly classifie[illegible]MSC. The mean age at death of the incorrectly classified group was lower (63.3 years) than the correctly classified group (74.5 years; $P < .00001$). There was a significant increase in misclassification over the 9-year period of study ($P = .02$). Autopsies were performed in only four cases, one of which (a noncutaneous, malignant fibrous histiocytoma) was misclassified. The incorrectly classified deaths did not differ from the correctly classified deaths with respect to gender or whether death occurred in a hospital (Table 1).

Table 2 displays the cause of death determined by examination of medical records of misclassified deaths. Striking trends were noted on comparison of the cause actually written on the death certificate by the certifying physician with the correctness of classification (see Table 3). If the problem categories of squamous-cell cancer or carcinoma of the neck or of the head and neck, cancer or carcinoma of the neck or of the head and neck, and malignant fibrous histiocytoma are eliminated, the accuracy of classification increases

This paper was submitted to the journal February 1, 1991, and accepted with revisions June 10, 1991.

from 46% to 88%, but only five (10%) of the correctly classified deaths are removed.

We received responses from 43 (81%) of the health departments to the single mailing of the questionnaire regarding actual coding practices. Two did not code cause of death themselves. There was no unanimity in coding for the three problematic categories described previously (squamous-cell cancer of the neck or of the head and neck, cancer of the neck or of the head and neck, and malignant fibrous histiocytoma), although for each the majority were consistent with the National Center for Health Statistics (NCHS) recommendations (see Table 4). Some states described inconsistencies in their coding of these diagnoses.

Fifty-five (50%) of the 110 deaths were classified under ICD 173.4 (scalp and neck). These included 48 (98%) of the mucosal carcinomas, the 1 lip carcinoma, and 6 (12%) of the correctly classified NMSC deaths.

Out of hospital	24	53

Note. ICD = *International Classification of Diseases.*

Discussion

We noted inaccurate classification of cause for over half of the reported NMSC deaths among Rhode Island residents. The vast majority of the misclassified deaths were due to mucosal squamous-cell carcinoma of the head and neck region. The vast majority of these could be distinguished from true NMSC deaths by examination of the death certificate. Coding of certain diagnoses has been inconsistent among health departments. The policy of coding squamous-cell carcinoma of the head and neck with NMSC (ICD-9 code 173) accounted for more than half of the misclassified deaths. Most (83%) of the misclassified deaths were coded under ICD 173.4.

Our study was subject to certain limitations. Postmortem examinations were rarely performed, although results of histopathologic examinations of relevant surgical specimens were available for almost all deaths. The documentation available in the medical records was frequently suboptimal. We adhered to specific criteria that required some evidence that the NMSC contributed to death; stricter criteria would have resulted in a higher proportion of unclassifiable cases, but our estimates of accuracy then might be biased since these unclassifiable cases would have been primarily individuals with advanced stages of NMSC and no documentation of the events immediately leading to death.

TABLE 2—Cause of Death Determined by Review of Medical Records among Deaths Misclassified as Nonmelanoma Skin Cancer: Rhode Island Residents, 1979–1987

Total	59	51

[a] Includes specific sites in the head and neck region (e.g., ear).
[b] Includes five deaths from malignant fibrous histiocytoma apparently arising deep to fascia.

The applicability of our findings to other areas of the United States is supported by the response of the Rhode Island Department of Health to our questionnaire. Their reported coding of cancer or squamous-cell cancer of the neck or of the head and neck was in accord with the practice reported by a majority of the health departments. A more thorough evaluation of the generalizability of our results awaits replication of our methods in other populations.

Prior investigations of the accuracy of NMSC death statistics are few. In 1970 through 1971, routinely coded death certificate diagnoses were compared with hospital diagnoses derived from the Third National Cancer Survey (TNCS).[8] Among the 67 deaths with the underlying cause NMSC (ICD-8 173) on the death certificate and with a hospital record of malignancy in the TNCS, only 18 (27%) were confirmed to have NMSC by the TNCS record abstract. These 18 also represented only 35% of the 51 deaths with any malignancy as the underlying cause and only NMSC noted in the hospital record abstract. Further evaluation of the medical records pertaining to these deaths was not performed.

Among 130 deaths coded as NMSC in California in 1959, 39 (30%) were determined to be due to NMSC, 73 (56%) were determined to be due to other causes, and, for 16 (12%), the cause could not be determined.[7] Among 133 NMSC deaths (i.e., coded under ICD-6 rubric 191) in Queensland, Australia, in 1960 through 1964, 95 (71%) on investigation were NMSC and 28 (21%) were other cancers.[9]

Most of the inaccuracies could be avoided by more consistent application of existing coding practices, by more uniform acceptance of the NCHS coding recommendations, and by changing the coding policy for squamous-cell cancer of the neck or head and neck to a rubric other than 173.

We must underscore the previously stated limitations in the interpretability of published NMSC mortality rates.[1,6,10,11]

TABLE 4—Coding Practices among the 41 Responding Health Departments[a] (United States, 1990)

Underlying Cause on Death Certificate:	ICD-9 Code	No. (%):
Malignant fibrous histiocytoma	173[b]	9 (22)
	171[c]	28 (68)
	216	4 (10)
Squamous-cell cancer of the neck	173[b,c]	38 (93)
	195	2 (5)
	199	1 (2)
Squamous-cell cancer of the head and neck (same responses as squamous-cell cancer of the neck)		
Cancer of the neck	173	2 (5)
	195[b,c]	39 (95)
Cancer of the head and neck (same responses as cancer of the neck)		

Note. ICD-9 = *International Classification of Diseases*, 9th version.
[a] In response to the question "Which ICD-9 code would you use to classify a death certificate with the following underlying cause listed on the death certificate?"
[b] Response of the Rhode Island Department of Health.
[c] The National Center for Health Statistics interpretation of the ICD-9 classification (M. Burt, personal communication, October 1990).

To best track the present epidemic of this very common cancer site, we need to complement existing sources of incidence data with refinements in the use of our primary source of mortality data: the death certificate. □

Acknowledgments

This study was supported by Department of Veterans Affairs medical research funds and National Cancer Institute Grant 49531.

A preliminary version was presented at the meeting of the Eastern Regional Society for Investigative Dermatology, New York City, October 1990.

We thank Margaret M. Boyle for her herculean efforts at locating medical records, and Roberta Chevoya, Joe Aldorissio, and John Fulton of the Rhode Island Department of Health for their assistance.

APPENDIX A—Criteria for Determining the Correctness of the Coded Cause of Death

Many of the records were traced and abstracted by a team of students (M.A., V.L., E.B., S.K.) in the last half of their final year of medical school. The remaining records were abstracted and the students' abstracts reviewed by a board-certified dermatologist (M.A.W.), who also adjudicated all ambiguities encountered by the medical student team and who was responsible for the final judgments regarding the correctness of the ICD classification according to the previously mentioned criteria. To resolve ambiguities in pathology reports, histologic specimens from certain biopsies were reviewed by a board-certified dermatopathologist (H.A.B.).

To accept a certificate as correctly coded under the ICD-9 rubric 173, we required that the diagnosis of nonmelanoma skin cancer be confirmed by medical records. We also required evidence from the record that the nonmelanoma skin cancer contributed significantly to the death. Some individuals did not die in medically supervised settings, or records of the events immediately leading to death were unavailable, so evidence of unresectable metastatic or advanced local disease (such as invasion of the orbital bones) was accepted as indicative of a significant contribution of the tumor to death. If the patient's physician believed that resection of extensive tumor was not feasible or not indicated because of the patient's poor prognosis, we considered the disease unresectable. We did not require that the available documentation of symptoms, signs, and tests convince us that the nonmelanoma skin cancer was the most important underlying cause of death. This degree of detail was often absent from the available documentation.

We determined that a certificate was incorrectly coded under the ICD-9 rubric 173 if we concluded from the record that the malignancy responsible for death was melanoma or arose from a noncutaneous primary site, or if the nonmelanoma skin cancer appeared unrelated to the events leading to death.

APPENDIX B—Description of the Six Deaths Excluded from Analysis

Two of the deaths involved individuals with aggressive AIDS-associated Kaposi's sarcoma. Since the ICD classification for this cause had changed from 173 to 042, we excluded these from the analysis. We were unable to verify or disprove the coded cause of death on the basis of medical records for four deaths. Complete records were obtained for two of these cases, but the primary site of the malignancy that led to death was unclear. In another two cases, we were unable to obtain complete medical records, either because the records were lost or destroyed or because the source of medical care during that time could not be traced. The nursing home at which one of these two patients last resided refused access to her medical records.

Provider Compliance with Recommended Dietary Fluoride Supplement Protocol

ABSTRACT

Proper dosage of dietary fluoride supplements is important for children without access to optimally fluoridated water to balance dental caries prevention and risks of dental fluorosis. Subsequent to water fluoride assay, compliance by physicians and dentists with the recommended dietary fluoride supplement dosage schedule was determined for 446 children. Approximately one third of child patients and 42% of siblings did not receive the recommended supplement dosage. (*Am J Public Health.* 1992;82:281–283)

Steven M. Levy, DDS, MPH, and Gary Muchow, MA, PhD

Introduction

Community water fluoridation remains the most efficient and cost-effective method to receive the recommended levels of fluoride for dental caries prevention.[1] Dietary fluoride supplements are advocated[2] for children not served by optimally fluoridated water (46% in the United States).[3]

Before prescribing supplements, fluoride histories and assays of the major sources of drinking water should be obtained in order to establish a balance between dental caries prevention and increased risks of dental fluorosis (mottled enamel).[2] Dental fluorosis is an enamel hypoplasia caused by the ingestion of excessive fluoride during the years of tooth calcification.[4] Water fluoride assay as a tool in preventing dental fluorosis is especially important in light of recent evidence of an increased prevalence of dental fluorosis,[4–6] of substantial prevalence nationwide,[7] and of the association of dietary fluoride supplement use with increased fluorosis risks.[6,8–11] The need for water fluoride assay to help avoid fluorosis has been emphasized recently in the US Department of Health and Human Services' review of the benefits and risks of fluoride.[12]

Table 1 shows the dietary fluoride supplement dosage schedule currently recommended.[13,14] Dosage is dependent on age and water fluoride level. There are many steps in the proper evaluation of dietary fluoride supplement need, dosage determination, and monitoring of patient compliance.[15] Many studies have reported difficulties with patient compliance,[16] but few have addressed provider compliance with recommended protocol.[17,18] A pilot study investigating the interactions that occurred between provid-

This paper was submitted to the journal October 15, 1990, and accepted with revisions June 10, 1991.

TABLE 1—Recommended Supplemental Fluoride Dosage Schedule[a] (in mg of fluoride per day)

Age of Child, y	Parts per Million of Fluoride in Water Supply		
	<0.3	0.3 to 0.7	>0.7
Birth to 2[b]	0.25	0	0
2 to 3	0.50	0.25	0
3 to 13[b]	1.00	0.50	0

[a]Recommended by the Council on Dental Therapeutics of the American Dental Association and the Committee on Nutrition of the American Academy of Pediatrics.
[b]The American Academy of Pediatrics recommends providing supplementation from 2 weeks of age through at least 16 years of age.

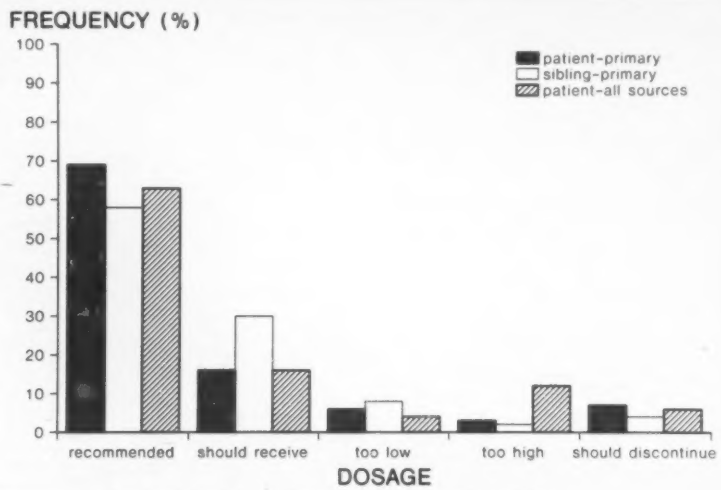

FIGURE 1—Appropriateness of dietary fluoride supplementation.

ers and patients subsequent to the submission of water samples for fluoride assay indicated that a substantial proportion of children were not receiving the appropriate levels of fluoride supplements.[15] The purpose of this study was to investigate further these patterns.

Methods

The State of North Carolina Laboratory of Public Health, the University of Iowa College of Dentistry, and the Iowa (State) Hygienic Laboratory provide assays of water samples for fluoride content, with results reported to the nearest 0.01 parts per million (ppm) of fluoride. The North Carolina laboratory uses an automated complexone method with distillation,[19] whereas the other two laboratories use fluoride ion-specific electrode techniques. The state laboratories are approved by the Environmental Protection Agency, and results have consistently been within 0.05 ppm of readings of Centers for Disease Control (CDC) blind standards.[20] The University of Iowa College of Dentistry does not participate in the CDC program but regularly performs several internal quality assurance checks. These three laboratories were chosen because of the differences in the individuals to whom results are reported. (The North Carolina laboratory reports results only to health care providers, Iowa College of Dentistry results may go to provider or patient, and Iowa state laboratory results usually are sent only to the patient, since the assay request form does not include provider information.)

Results of 647 samples submitted for fluoride assay between March 1987 and February 1989 were analyzed. Parents of 548 patients (or 85%) were successfully contacted 3 to 4 months after the assay results were sent, permitting provider/patient follow-up to occur before our survey was administered. Thirty-nine percent of the samples were analyzed at the North Carolina state laboratory, 36% at the Iowa College of Dentistry, and 24% at the Iowa Hygienic Laboratory.

Results

Subsequent to the reporting of the assay results, contacts occurred between parents and health care providers in 85% of the cases. Eight percent were with a second provider, either instead of or in addition to the provider who recommended the assay (e.g., a physician recommended assay and a dentist was contacted to assist with interpretation of the results).

More than half of the parents reported that their child received substantial amounts of water outside of the home (34% child care and 22% school), but only 29% reported that the provider inquired about additional sources of water.

Prescriptions for dietary fluoride supplements (tablets or drops) were provided for 75% of the patients. Eighteen percent were prescribed prior to the assay, with the provider probably assuming negligible levels of fluoride in the drinking water and prescribing full dosage supplements. However, only about half of the samples in Iowa and 80% to 85% in North Carolina had fluoride content less than 0.3 ppm.[15,21,22]

Using patient age, assay results, and recommended dosage schedules, determinations were made as to the appropriateness of the fluoride supplement received by patients and siblings based on their reported primary source of water. Because of incomplete information, such determinations were not possible for 19% of the patients and 12% of the siblings. The results (Figure 1) exclude these "unknowns."

Sixty-nine percent of the patients received the recommended dosage (including no supplement, when indicated) after the assay results had been reported. Sixteen percent were not receiving a supplement when indicated, and 6% needed a supplement at a higher dosage. Three percent should have received reduced dosage, and 7% needed supplementation discontinued.

Fifty-eight percent of the siblings received a correct dosage. Thirty percent of siblings were not receiving a fluoride supplement when one was indicated. These siblings could have received appropriate supplementation without further assay of their home drinking water being necessary. Eight percent needed a supplement at a higher dosage, 2% needed a lower dosage, and 4% needed supplementation discontinued.

Appropriateness of supplementation was also determined for patients based on weighting of multiple patient sources of drinking water (e.g., home, school, and day care). This determination of appropri-

ateness was made only in those cases where additional fluoride assay was not necessary because the additional sources involved community water systems of known fluoride content. Sufficient information to determine appropriateness in this way was available for 342 patients. Among these, 63% received a correct dosage of fluoride. Sixteen percent did not receive a supplement when one was indicated, 4% needed a higher dosage, 12% needed a lower dosage, and 6% needed to stop supplementation.

Discussion

The findings are consistent with those of our previous pilot study. Approximately one third of patients for whom water fluoride assay was performed did not receive the recommended dosage of the dietary fluoride supplement. Among these, about one third were at increased risk of dental fluorosis and two thirds were not receiving the recommended level for caries prevention. Siblings were less likely to be receiving the recommended supplement dosage. These results likely are conservative estimates of discrepancies among all providers, because the patients and providers in this study probably were more knowledgeable and/or motivated, as evidenced by their assay efforts.

Since more children are receiving substantial proportions of drinking water outside the home, patient water sources other than at home were considered. This often was important when home drinking water was nonfluoridated but water at child care or school was optimally fluoridated. Following the "standard practice" of considering fluoride from the home source only and providing a dietary fluoride supplement would place the child at higher risk of dental fluorosis. Thus, as suggested previously,[21,22] it probably is now appropriate to consider all important water sources, including those other than home, in the standard approach and to weight proportionately the ingestion from multiple water sources and the fluoride levels. As always, adjustments of supplement dosage are necessary as children turn ages 2 and 3, even where fluoride content of important water sources remains the same.

The reporting systems in this study supplied the provider or parent with water fluoride assay results but not with information for interpretation of the results. Most laboratory reports for other types of analyses provide information about the range of "normal" laboratory values. In order for appropriate fluoride supplements to be prescribed more consistently, it may be advisable for laboratories to include with their assay results an insert with dosage schedule and guidelines for interpretation of results. In addition, public health personnel must consider the cost–benefit ratio of dietary fluoride supplement and water assay programs. Especially in those states without existing water fluoride assay programs,[23] it may be appropriate for dietary fluoride supplements and water fluoride assay to be used only with children at high risk of dental caries. □

Body Fatness and Risk for Elevated Blood Pressure, Total Cholesterol, and Serum Lipoprotein Ratios in Children and Adolescents

Daniel P. Williams, MS, Scott B. Going, PhD, Timothy G. Lohman, PhD, David W. Harsha, PhD, Sathanur R. Srinivasan, PhD, Larry S. Webber, PhD, and Gerald S. Berenson, MD

ABSTRACT

Background. Recent studies have shown considerable variation in body fatness among children and adolescents defined as obese by a percentile rank for skinfold thickness.

Methods. We examined the relationship between percent body fat and risk for elevated blood pressure, serum total cholesterol, and serum lipoprotein ratios in a biracial sample of 3320 children and adolescents aged 5 to 18 years. Equations developed specifically for children using the sum of subscapular (S) and triceps (T) skinfolds were used to estimate percent fat. The S/T ratio provided an index of trunkal fat patterning.

Results. Significant overrepresentation (>20%) of the uppermost quintile (UQ) for cardiovascular disease (CVD) risk factors was evident at or above 25% fat in males (32.2% to 37.3% in UQ) and at or above 30% fat in females (26.6% to 45.4% in UQ), even after adjusting for age, race, fasting status, and trunkal fat patterning.

Conclusions. These data support the concept of body fatness standards in White and Black children and adolescents as significant predictors of CVD risk factors. Potential applications of these obesity standards include epidemiologic surveys, pediatric health screenings, and youth fitness tests. (*Am J Public Health.* 1992;82:358–363)

Introduction

The association between skin-fold thicknesses in children and adolescents and elevated levels of variables considered to be indicative of risk for cardiovascular disease (CVD) in adults has been found by several investigators.[1–5] In population-based studies of children and adolescents, for example, excess subcutaneous fatness has been associated with elevated blood pressure (BP),[1,2,6] serum lipids, and lipoprotein fractions,[2–4] and the clustering of these variables.[5] Although the results of these studies demonstrate that elevated levels of CVD risk factors often accompany excess body fat in youth, the absolute level of body fat corresponding to significant risk for high BP, serum lipids, low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) cholesterols is not known.

Although children and youth with triceps skinfolds ≥ the 85th percentile for age and sex are at greater risk for high BP than children with lower skinfold thicknesses,[1] such a rank-ordered definition of obesity implies that the absolute level of body fatness associated with increased risk is variable. Recent work has shown that the 85th percentile may not be indicative of obesity in all samples, because skinfold thicknesses at a given percentile correspond to different levels of body fat at different ages.[7,8] The 85th skinfold percentile, for example, represents fatness levels ranging from 17% to 22% in children and from 25% to 34% in adolescents.[8]

In addition to the discrepancy between relative and absolute definitions of obesity, the triceps skinfold site has been shown to be unrelated to BP in youth when statistical adjustments were made for subscapular skinfold thickness.[9] Moreover, a trunkal fat pattern, independent of general body fatness, is related to high levels of LDL and VLDL and to low levels of high-density lipoprotein (HDL) cholesterol in 6- to 18-year-old youth.[10] The independent effects of centripetal localization of subcutaneous fat on BP[9,11] and adverse lipoprotein profiles[10] make it important to control the potential confounding effect of fat patterning when the relation between total body fat and CVD risk factors in youth is evaluated.

The purpose of the present study was to determine the level of body fatness, independent of fat patterning, associated with significant risk for elevated BP, total cholesterol, and serum lipoprotein ratios in a biracial sample of children and adolescents aged 5 to 18 years. The aim was to develop cardiovascular health-related percent body fat standards that may be applied to epidemiologic investigations of the prevalence and incidence of obesity in children and adolescents, pediatric health screenings, and national youth fitness tests.[12,13]

Methods

Study Sample

The sample included 1667 males (1062 White, 605 Black) and 1653 females (1028 White, 625 Black) aged 5 to 18 years. All subjects were residents of Ward 4, Washington Parish, La, and were participants in the Bogalusa Heart Study. The data were collected in the years 1983 through 1985. An extensive review of the demographic characteristics of this biracial community, as well as the overall design of this large, population-based investigation of children and youth, has been published elsewhere.[14] The Louisiana State University Medical Center reviews experiments related to human subjects. Written informed consent was obtained from a parent or guardian of each child.

Procedures

Total body fat and fat distribution. Total body and regional fatness were estimated from limb (triceps) and trunk (subscapular) skinfold thicknesses. Lange calipers were used to measure triceps and subscapular skinfolds to the nearest 1.0 mm. Skinfold measurement technique and site location have been described previously.[14,15] The reliability of these measurements, assessed by test-retest intraclass correlations, was of equal magnitude ($r = 0.98$) for both sites.[16]

Body density (D_b) was estimated from age and the sum of triceps and subscapular skinfolds (STSS) and was subsequently used to derive total percent body fat. The STSS-to-D_b conversion was based on race- and gender-specific regression equations that were derived from the pooled skinfold and body density data from several samples of White and Black youth measured in different laboratories (Appendix).[17–20] We then used a modification of the density–to–percent-fat conversion constants reported by Lohman[21] to convert D_b to percent body fat (Table 1, Eqs. 1 and 2). These youth-specific constants adjust for growth- and maturation-related differences in fat-free body density (D_{FFB}) at different ages and prevent the systematic overestimation of body fat when adult density–to–percent-fat equations are applied to chemically immature children and youth.[22] The present combination of equations was chosen over other multicomponent-based equations for youth that convert STSS directly to percent fat[23] because the multilaboratory equations used herein may be more generalizable.

TABLE 1—Multilaboratory-based Estimation of Body Density from the Sum of Triceps and Subscapular Skinfolds (STSS) and Age in White and Black Children and Adolescents[a]

Variable	Males		Females	
	White (n = 262)	Black (n = 96)	White (n = 219)	Black (n = 94)
STSS (mm)	−0.00227	−0.00203	−0.00188	−0.00162
STSS^2 (mm^2)	0.000015	0.000012	0.000013	0.000008
Age, yr	0.00243	0.00193	0.00191	0.00165
Intercept	1.0600	1.0682	1.0533	1.0580
Adjusted intercept		1.0666		1.0555
R^2	0.70	0.65	0.58	0.70
SEE (g/cm^3)	0.0102	0.0107	0.0096	0.0089

[a]Because currently available equations for converting body density (D_b) to percent fat[21] are based more on the fat-free body composition of Whites than of Blacks, we adjusted the intercepts in the above equations for Black males and females to remove the influence of differences in fat-free body density (D_{FFB}) on D_b and, subsequently, on estimates of body fat. Body density was converted to body fat using age-adjusted, gender-specific equations derived by regression analysis from age and the recently reported age-specific body density constants,[21] thereby deriving the following equations to estimate percent fat (PF) from D_b:

(1) $PF_{males} = [(5.68 - (0.041 \times age)) \div D_b] - [(5.31 - (0.045 \times age))] \times 100$

(2) $PF_{females} = [(5.69 - (0.038 \times age)) \div D_b] - [(5.31 - (0.041 \times age))] \times 100$

To determine the critical level of body fat associated with elevated CVD risk factor variables, the males and females were subsequently grouped by level of percent fat. Males were divided into the following five fatness groups: <10% (n = 217), 10% to 14.9% (n = 575), 15% to 19.9% (n = 436), 20% to 24.9% (n = 192), and ≥25% (n = 247). Females were grouped by body fat as follows: <20% (n = 547), 20% to 24.9% (n = 493), 25% to 29.9% (n = 313), 30% to 34.9% (n = 192), and ≥35% (n = 108).

An index of trunk-to-limb fat distribution was computed as the natural logarithm of the subscapular/triceps skinfold thickness ratio.[24] Because absolute standards for children and youth do not exist for this index of fat patterning, age-, sex- and race-specific percentiles for the present sample were developed. Fat-patterning quintile, used as a covariate of percent fat in this report, refers to the contrast of youth in the uppermost quintile for $\log_n$ (subscapular/triceps) with those in the lower four quintiles. This contrast was used in the analysis to control for the potential confounding effect of trunkal fatness in assessing the relation of total body fat with BP[9] and serum lipoproteins.[10]

CVD risk factor variables. The protocol, standardization, and training of observers used to measure BP[14] and the blood collections required to assess serum total cholesterol and lipoprotein levels[3] have previously been outlined in detail. Seated, resting BP measures on the right arm were made in triplicate with a mercury sphygmomanometer by trained nurses; the mean of six readings at the first (systolic) and fourth (diastolic) Korotkoff sounds was used in the data analysis. In an earlier Bogalusa Heart Study survey, reliability coefficients ranged from $r = .84$ to $r = .86$ for systolic BP and from $r = .76$ to $r = .78$ for diastolic BP.[16]

Serum total cholesterol and lipoproteins were measured at Louisiana State University Core Lipid Laboratory, New Orleans, La, which has been standardized by the Centers for Disease Control in Atlanta, Ga. Laboratory measurement quality is routinely monitored by a surveillance program. Serum total cholesterol concentration was measured with an AutoAnalyzer II, according to the recommendations of the Lipid Research Clinics.[25] A combination of heparin-calcium precipitation and agar-agarose gel electrophoresis[26] was used to determine the levels of lipoprotein cholesterol fractions (VLDL-C, LDL-C, and HDL-C). Reliability coefficients (intraclass correlations) ranging from $r = .89$ to $r = .97$ were reported earlier for these variables.[16]

For the purpose of this report, elevated BP, total cholesterol, and lipoprotein cholesterols were individually defined as levels in the uppermost quintile of the age-, race-, and sex-specific distributions for systolic BP, diastolic BP, total cholesterol, the LDL-C/HDL-C ratio, and the ratio of VLDL-C + LDL-C/HDL-C. The uppermost quintile was chosen to define elevated CVD risk factor variables because an earlier study[27] demonstrated this cutoff point to be a more sensitive indica-

tor of future high BP than was the more stringent 95th percentile.

Data analysis. A chi-square test was used to determine whether the percentages of subjects in the fifth quintile for BP, total cholesterol, and lipoprotein ratios were significantly different than those expected by chance alone (20%) at each level of body fatness in both sexes. Logistic regression analysis[28] was used to estimate the relative odds for elevated BP, total cholesterol, and lipoprotein ratios between contrasting percent fat groups of interest, while holding potential confounders constant. Presence or absence of elevated BP, total cholesterol, and lipoprotein ratios were the dependent variables in the logistic regression analyses. The independent variables included several percent fat group contrasts; a contrast for fat-patterning quintile; race; age; and, for the total cholesterol and lipoprotein ratio analyses, fasting status. The risk for membership in the uppermost quintile for the cardiovascular variables was defined as 1.00 in the lowest percent fat group. The odds of uppermost quintile membership were thus determined for each of the upper four percent fat groups relative to the leanest group within each gender.

Results

The unadjusted bivariate relationships between body fat and CVD risk factor variables is shown in Table 1. A dose-response effect was observed between BP and percent body fat; in contrast, total cholesterol and the lipoprotein ratios were relatively independent of percent body fat among the lower four fatness groups in males and the lower three fatness groups in females (Table 2). The percentage of subjects in the uppermost quintile for all CVD risk factor variables was significantly ($P < .05$) greater than that expected by chance alone (20%) in males with ≥25% fat and in females with ≥30% fat. The ≥35% fat group of females displayed even greater overrepresentation (31.0% to 45.4% vs 26.6% to 33.2%) in the uppermost quintile than did the 30% to 34.9% fat group of females.

Multivariate-based estimates of the relative odds for elevated BP, total cholesterol, and lipoprotein ratios, adjusted for potential confounding variables at increasing levels of percent body fat, are presented in Figure 1 for males and Figure 2 for females. After accounting for potential confounding by age, race, trunkal fat patterning, and fasting status, males with body fat ≥25.0% were 2.8 (1.7–4.8) to 7.0 (3.6–13.6) times as likely as those in the leanest group (<10% fat) to have elevated systolic BP, diastolic BP, LDL-C/HDL-C ratios, and VLDL-C + LDL-C/HDL ratios (Figure 1). In females, the 30% to 34.9% fat group was 2.7 (1.6–4.5) to 3.8 (2.3–6.1) times more likely than the leanest group (<20% fat) to be in the uppermost quintile for these CVD risk factor variables; the likelihood for elevated BP and lipoprotein ratios in the female ≥35.0% fat group ranged from 3.3 (1.8–5.9) to 4.9 (2.8–8.7) (Figure 2).

Discussion

This study is unique because critical levels of body fat, as opposed to skinfold thickness percentile, that correspond to significant risk for elevated BP and lipoprotein ratios were determined and found to be independent of trunkal fat patterning in a biracial sample of children and youth. Inherent in previous normative value-derived definitions of childhood obesity[1] is the considerable age-related variation in body fatness at a constant percentile for skinfold thickness.[7,8] This concept is supported by the finding that the 85th percentile for the STSS in the present sample of children and adolescents represents body fatness values ranging from 14.8% to 34.3% fat in males and from 21.9% to 37.7% fat in females. Moreover, the finding that critical levels of body fatness were related to elevated levels of CVD risk factor variables independent of trunkal fat patterning is particularly relevant in light of recent studies[5,10,29] establishing the link between trunk fatness and high levels of BP, serum lipoprotein fractions, and serum insulin in children and adolescents. The independent relationships of CVD risk factors with percent body fat in children and adolescents and with trunkal fat patterning in adolescents[30] suggest that measurement of both total and regional

fatness may be informative, especially for adolescent health screenings.

The magnitude and statistical significance of the odds for uppermost quintile membership at increasing levels of body fat, relative to the leanest group, were somewhat greater for the BP variables than for the lipoprotein variables (Figures 1 and 2). This difference in adjusted odds ratios between the BP variables and lipoprotein ratio variables may best be explained by differences in uppermost quintile membership rates within the leanest reference groups (<10% fat, males; <20% fat, females). In males, for example, for whom the difference in odds ratios between the BP variables and lipoprotein ratio variables at each level of body fat was most evident, the reference body-fat group was significantly protected against elevated BP but not against elevated lipoprotein ratios (Table 2). The trend observed in males—for the lowest risk for elevated lipoprotein ratios to occur in the 10% to 14.9% fat group—somewhat parallels the trend for higher mortality rates in the lowest-weight-for-height group than in the middle-weight-for-height group observed in adult participants of the Framingham Study.[31] However, none of the middle percent-fat groups was significantly more protected against elevated total cholesterol or lipoprotein ratios than was the leanest group (Figure 1).

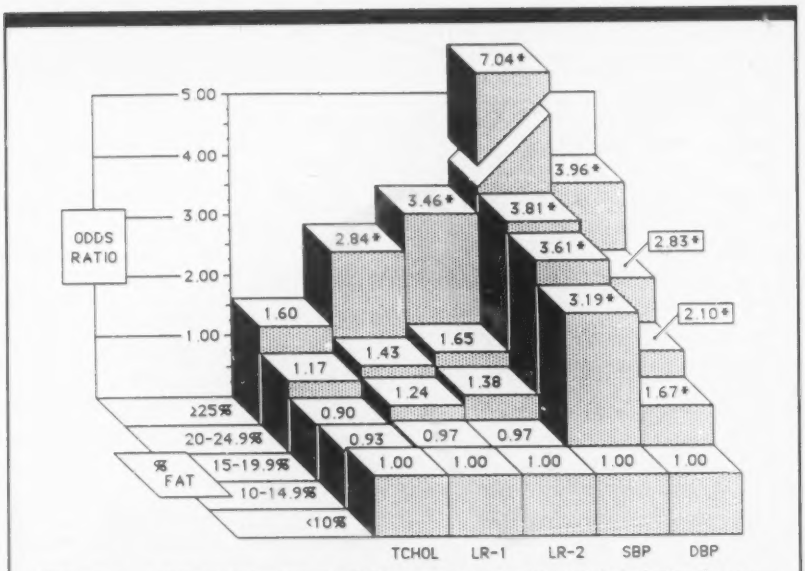

FIGURE 1—Adjusted estimates of relative odds for elevated total cholesterol, serum lipoprotein ratios, and blood pressure in males (*95% CI does not include 1.00). Abbreviations are the same as in Table 2.

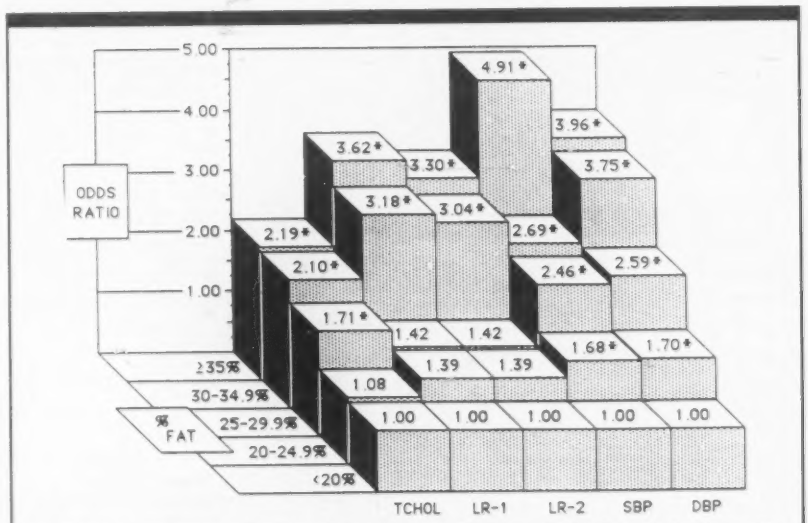

FIGURE 2—Adjusted estimates of relative odds for elevated total cholesterol, serum lipoprotein ratios, and blood pressure in females (*95% CI does not include 1.00). Abbreviations are the same as in Table 2.

In an analysis of national survey data, 6- to 11-year-old children with triceps skinfold thicknesses at or above the 85th percentile were found to be 2.6 and 1.6 times as likely as their leaner peers to have elevated systolic BP and diastolic BP, respectively.[1] Similarly, in 12- to 17-year-old youth, the risks for elevated systolic BP and diastolic BP were 4.3 and 6.1 times higher, respectively in youth having skinfold thicknesses equal to or exceeding the 85th percentile. Although the odds ratio estimates from the present study compare reasonably well with those reported previously for adolescents, they are somewhat higher than those reported for children.[1]

Several differences between the present study and the national survey analysis may account for the discrepancies in the reported relationships between body fatness and elevated BP. The 85th percentile for triceps skinfold thickness was used as an index of body fat in the previous study,[1] whereas in the present study, percent body fat was estimated from the STSS. Also, the previous study[1] referenced youth of both sexes with skinfold thicknesses equal to or exceeding the 85th percentile against those with skinfold thicknesses below the 85th percentile; however, in the present study, we contrasted four separate gender-specific percent fat groups at 5% intervals against the leanest males (<10% fat) and females (<20% fat), as appropriate. In addition, elevated BP was defined with a more stringent cutoff point (≥95th percentile) in the previous study[1] than was used in this study (≥80th percentile). Finally, in the present study, potential confounding by fat patterning was statistically controlled by using a contrast for the quintile level of $\log_n$ (subscapular/triceps); seasonality, but not fat pattern, was controlled in the previous investigation.[1]

Because a relative index of body fatness corresponding to the 85th percentile for triceps skinfold thickness was used in the earlier study,[1] it is not surprising that substantially lower estimates of risk were observed in the younger children than in the adolescents. In the present study, for example, the STSS corresponding to the

85th percentile results in percent-fat estimates of 14.8% in a 6-year-old Black male and 34.3% in a 12-year-old Black male. This age-related change in percent-fat estimates is due to the greater STSS at the 85th percentile at age 12 than at age 6 (54.8 vs 17.3 mm), and not to inaccuracies introduced by the conversion of the STSS to percent fat in children of different ages. The age-adjusted, gender- and race-specific equations used to estimate density from the STSS in the present study correct for the age-related change in the skinfold–to–density relationship in youth.[22] Moreover, the age-adjusted gender-specific equations used to convert the predicted densities to percent fat were derived from a multicomponent body composition model that accounts for age-related differences in the water and bone mineral content of the fat-free body that are associated with growth and development.[21,22]

Individual skinfold thicknesses may be inaccurate indicators of body fatness, inasmuch as a constant skin-fold thickness corresponds to a different body density and percent body fat at different ages[22] and in different races.[23] In the present study, with percent body fat calculated with an age- and race-specific approach, logistic regression coefficients were all nonsignificant for race ($P > .05$), and age was significant only for BP in males. With respect to age, statistical control for a constant relative rank of trunkal fat patterning may have exerted a stronger effect in the older adolescents than in the younger children owing to the pubescence-related increase in the absolute amount of centrally located body fat.[24,30] Thus, the body fat standards recommended in this study (≥25% for males, ≥30% for females) appear to be generally applicable throughout the 5- to 18-year-old biracial sample reported herein. However, possible biases due to subject selection, nonresponse, and geographic location may limit the generalizability of these standards, and point to the need for further validation of these standards in national probability-based samples.

On the basis of the present findings, we conclude that fatness levels at or above 25% in males and 30% in females are indicative of increased risk for elevated BP and lipoprotein ratios in White and Black children and adolescents. These new body fatness standards are applicable not only to epidemiologic studies of the prevalence and incidence of obesity in children and adolescents, but also to pediatric health screenings and health-related tests of youth fitness.[12,13] Previous studies have defined childhood obesity with age- and sex-specific values for triceps skinfold thickness[1] or weight for height[32] that correspond to critical positions in a reference population. The use of norm-referenced standards to distinguish between obese and nonobese persons is limited by the fixation of obesity prevalence to a certain percentage of a population[33] at a particular point in time and by the considerable variation in body fatness at a constant percentile of skinfolds or weight for height.[7,8] Our findings support the concept of body fatness standards as significant predictors of CVD risk factors in children and youth. Furthermore, this study offers an empirically determined alternative to current normative-based definitions of childhood obesity. Future studies in longitudinal cohorts that make direct comparisons between critical percent fat and skinfold thickness percentile cutoff points are needed to assess the specificity and sensitivity of the two screening tools. □

Acknowledgments

This research was supported by USPHS grant HL 38844 from the National Heart, Lung, and Blood Institute.

We are sincerely grateful to the children and parents of Bogalusa, La, whose participation and cooperation made this study possible. We also wish to thank Michael J. Hewitt, PhD, for his work on the illustrations.

This paper was presented in part at a symposium on youth fitness during a meeting of the Southwest Chapter of the American College of Sports Medicine in San Diego, Calif, December 1990.

Deadline for Student Papers on Injury Is March 31, 1992

The Southern California Injury Prevention Research Center is pleased to announce a competition for the best student papers in 1991 on injury. Papers must focus on public health aspects of intentional injury (homicide, suicide, sexual assault, battering, child abuse, etc.) or unintentional injury (motor vehicle crashes, falls, drowning, burns, etc.). Priority will be given to original scientific contributions that focus on injuries in ethnic or racial minorities, the poor, and other traditionally underserved populations.

Three awards are anticipated in the amounts of $500, $250, $150 for manuscripts that demonstrate original methods in injury research, analyze new data, or emphasize findings with countermeasure potential. The award will be made directly to the student in recognition of his or her contribution to injury research.

Although papers published in 1991 will be considered, the submission of unpublished manuscripts is strongly encouraged. Papers should be submitted by the student or by an academic adviser on behalf of the student and with his or her permission. If unpublished, the manuscript (including references and tables) should not exceed 30 double-spaced pages. In addition to the manuscript, a letter from the student's adviser should be submitted which verifies that the work and writing were conducted by the student who was enrolled in graduate training during 1991. Full acknowledgment of the student's primary role in the work should be reflected through his or her first authorship of the paper. All submissions must include student's name, address, and daytime telephone number. Manuscripts should be prepared according to the *American Journal of Public Health* style guidelines and submitted in triplicate to Jess F. Kraus, PhD, Southern California Injury Prevention Research Center, UCLA School of Public Health, 10833 Le Conte Avenue, Los Angeles, CA 90024-1772. The deadline for submissions, which was omitted from the previous announcement in the January issue of the *American Journal of Public Health,* is March 31, 1992.

Inquiries may be directed to Renee Goetz, MSW, Administrative Coordinator, at the same UCLA address (telephone 213/206-4115).

Childhood Chronic Illness: Prevalence, Severity, and Impact

ABSTRACT

Background. Using data from the 1988 National Health Interview Survey, this article presents national estimates of the prevalence and impact of childhood chronic conditions.

Methods. Proxy responses to a checklist of child health conditions administered for 17 110 children under 18 years of age were used. Conditions were classified as chronic if they were first noticed more than 3 months prior to the interview or if they were the type that would ordinarily be of extended duration, such as arthritis.

Results. An estimated 31% of children were affected by chronic conditions. Among these children, highly prevalent conditions included respiratory allergies 9.7 per 100, repeated ear infections 8.3 per 100 and asthma 4.3 per 100. These children can be divided into three groups: 66% with mild conditions that result in little or no bother or activity limitation; 29% with conditions of moderate severity that result in some bother or limitation of activity, but not both; and 5% with severe conditions that cause frequent bother and limitation of activity. The 5% with severe conditions accounted for 19% of physician contacts and 33% of hospital days related to chronic illness.

Conclusions. Childhood chronic conditions have highly variable impacts on children's activities and use of health care. (*Am J Public Health.* 1992;82:364–371)

Introduction

Childhood illness has changed dramatically in the United States during this century. Infectious diseases that claimed the lives of thousands of children during the early 20th century have been largely eliminated through improvements in infectious disease control, sanitation, housing, and medical care. Mortality rates have fallen from 870 per 100 000 children aged 1 to 14 years in 1900 to 33 per 100 000 children in 1987.[1] But although this trend demonstrates progressive improvements along one critical dimension of child health, reductions in the prevalence of childhood chronic illness have not been nearly as dramatic.[2]

True, the prevalence of some childhood chronic conditions, such as polio and rheumatic fever, has declined markedly in the second half of this century. However, dramatic medical advances in the last few decades have resulted in many chronically ill children, who previously would have died much earlier from their illnesses, now surviving into adulthood. For example, there is evidence of a sevenfold increase in survival to age 21 among children with cystic fibrosis and of twofold or greater increases in survival for children with spina bifida, leukemia, and congenital heart disease.[3,4] Moreover, evidence from other quarters, albeit more controversial, suggests that the prevalence of non-life-threatening chronic conditions may have increased in recent years. According to national household survey data, the prevalence of asthma severe enough to limit a child's activities increased by 65% during the 1970s. Similar increases were reported for hearing impairments and a variety of mental and nervous system disorders.[5]

Despite concern over these trends, knowledge of the prevalence and distribution of childhood chronic illness is limited.[6] Indeed, there are not even accepted criteria for defining childhood chronic illness. Partly because such common definitional criteria are lacking, the research community has generated widely differing estimates of the prevalence of childhood chronic conditions. Additional variation results from the different methods used in collecting prevalence data. Some studies are population based; others are clinic based. Some rely on parental reports; others use medical records. Some include only chronic physical conditions; others include physical and mental conditions. As a result of these different methods, published estimates of the proportion of children with one or more chronic illnesses range from less than 5% to more than 30%.[7–13]

The present study provides estimates of the prevalence of childhood chronic conditions from a large population-based sample of children included in the National Health Interview Survey (NHIS) on Child Health.[14] Using this survey to derive prevalence estimates offers a number of advantages. First, a population-based sample provides for more representative results than could be obtained from a sample of patients appearing at clinics, hospitals, or other treatment centers. Second, a nationally representative sample eliminates geographic biases that might result

from localized small-area samples. Third, the large sample size (n = 17 110) permits more precise prevalence estimates than could be obtained from smaller samples.

Data from the survey are used in this paper to examine the national prevalence of childhood chronic illness. We present prevalence estimates for 19 different categories of chronic conditions and estimates of the number of children with multiple chronic conditions. We describe how prevalence varies according to age, gender, and race. We examine the impact of chronic conditions on children's activity levels and show how childhood chronic conditions influence children's use of health services. Finally, we show how prevalence estimates change when different severity thresholds are applied.

Methods

The NHIS is a continuing nationwide survey conducted by the Bureau of the Census for the National Center for Health Statistics (NCHS). Its purpose is to collect information on the health status and use of health care by the US population. The sample is designed to be representative of the US civilian noninstitutional population.[14]

In 1988, a special supplemental questionnaire on child health was included in the survey. This questionnaire, similar to one used in 1981, covered a range of topics relevant to child health, including child care, pregnancy and birth, behavioral problems, developmental problems, other child health problems, and use of health services. One child in each household was selected at random to be the subject of the supplemental interview. An adult member of the household knowledgeable about the child's health served as the respondent. In about 90% of the cases, the respondent was a parent of the sample child, usually the mother. Interviews were completed for 91% of all eligible children, resulting in a sample of 17 110 children under 18 years old.[15]

Of particular importance was the inclusion in the supplement of a detailed checklist of childhood health conditions. The checklist was oriented toward recurrent or chronic conditions. Respondents were read this extensive list and asked whether the sample child had any of the included conditions during the previous 12 months. From these results, annual prevalence estimates can be derived for a variety of childhood health problems as diverse as repeated ear infections, cerebral palsy, and juvenile arthritis—but excluding minor acute illnesses, such as colds and the flu. In part because of past problems of underreporting, cancers and mental health problems without physical manifestations were excluded from the checklist.

Data on the impact of checklist conditions were also collected in the supplement. Each time a condition was reported as present during the previous year, a set of follow-up questions was asked about the frequency and amount of bother caused by the condition; the days spent ill in bed; the days missed from school; and the resultant use of medications, physician services, and hospital care. Together, these data permitted analysis of the impact of chronic conditions on children's activity levels and health care use patterns. The questions and probes used to identify the impact of chronic conditions are reproduced in Appendix A.

Data on school absences and days in bed were not collected for children experiencing hearing, vision, or speech problems or eczema and skin allergies on the assumption that these conditions result in few, if any, bed days or school absences. A follow-up question on limitations in play and sports activities was included in the supplement but was asked only for children with certain chronic conditions. However, the core questionnaire contained questions that were asked for all children regarding limitation of activity due to chronic conditions, and those results are used here. With the results from those questions, children were classified as limited in their activities if they were reported as being limited in or unable to conduct age-appropriate activities, such as school or play.

We asked a panel of eight pediatricians to review the 76 checklist conditions to determine whether any should be excluded from our analysis of chronic conditions. When a majority considered a condition not to be chronic, that condition was eliminated. A total of eight conditions were eliminated in this fashion. We then classified the remaining conditions according to chronicity using conventions similar to those developed by the NCHS's Division of Health Interview Statistics. Specifically, a condition was considered chronic if (1) the respondent indicated it was first noticed more than 3 months before the interview date, or (2) it was a type of condition that ordinarily has a duration of more than 3 months.[16] Examples of conditions that are considered chronic regardless of their time of onset include diabetes, heart conditions, and arthritis.

Because no severity criteria are used, this approach to defining chronic illness leads to the inclusion of a large number of conditions and thus provides an upper-bound estimate of the size of the chronically ill child population. We show how prevalence estimates diminish when we use more restrictive definitions that take into account the impact or severity of reported conditions.

To enable a manageable analysis and presentation, we grouped conditions into 19 broader categories, including 5 impairment groupings and 14 disease groupings. This categorization scheme is based on grouping conditions that are clinically related while taking into account constraints due to sample size limitations. The disease categorization includes conditions with active pathology whereas the impairment categorization includes conditions with stable pathology. The overall categorization scheme and condition groupings are illustrated in Appendix B.

The actual number of sample cases is presented in the first column of Table 1 and Table 2. All other results are weighted to reflect national population estimates. The weights were provided by NCHS and are equal to the inverse of the sampling probability for each sample child. Standard errors were calculated using software designed to take into account the complex sample design of the NHIS.[17,18]

Results

Prevalence of Childhood Chronic Conditions

As shown in Table 1, an estimated 31% of children under 18 years of age, or almost 20 million children nationwide, were reported to have one or more chronic conditions in 1988. Although most chronically ill children were affected by a single condition, a significant minority were afflicted by multiple chronic conditions. Among children with chronic conditions, 70% were reported to have one checklist condition, 21% had two, and 9% had three or more. It is likely that these estimates understate the true size of the child population with single and multiple conditions, given that not all childhood chronic conditions—particularly those related to mental health—were included in the checklist.

As shown in Table 2, the most commonly reported childhood chronic conditions included respiratory allergies (including hay fever) and frequent or repeated ear infections. Respiratory aller-

gies affected 97 of every thousand children and 83 of every thousand children experienced repeated ear infections. Other relatively common conditions included asthma, eczema and skin allergies, frequent or severe headaches, and speech defects. Each of these had a prevalence of 25 per 1000 or more. Conditions of low prevalence included diabetes, sickle cell disease, and cerebral palsy, each of which affected fewer than two of every thousand children in the United States.

Prevalence of childhood chronic conditions is shown in Table 3 to vary by demographic status. Although chronic conditions appear slightly more prevalent among older children (315 per 1000) than among younger children (302 per 1000), the difference is not statistically significant. However, chronic conditions were more prevalent among boys (326 per 1000) than among girls (288 per 1000), and among White children (324 per 1000) than among Black children (247 per 1000).

Impact of Childhood Chronic Conditions on Children's Health

The questionnaire included several measures of the impact of chronic conditions on children's health. Included among these was both the frequency and the amount of bother caused by the condition. On average, childhood chronic conditions were reported to never bother children 25% of the time, bother them once in a while 53% of the time, and bother them often or all the time 22% of the time (Table 4). The amount of bother caused by childhood chronic conditions ranged, on average, from a great deal of bother (25%) to very little or some bother (50%) to no bother at all (25%).

The survey also collected information on limitation in usual activities and on average annual bed days and school absences (Table 5). Overall, 13% of children with one or more chronic conditions were classified as limited in their usual activities. Children with one or more chronic conditions experienced an average of slightly more than 2 bed days and 3 lost school days in the previous year. These bed days and school absences are in addition to those resulting from acute conditions such as colds, the flu, and minor injuries. Hence, they represent the added burden of chronic illness for these children.

The average numbers of bed days and school absences presented in Table 5 mask large differences among individual children even with the same condition. In fact, bed days and lost school days were quite unevenly distributed among children with chronic conditions. Most children experienced no bed days or school absences in 1988 that could be attributed to chronic conditions; it was just a small segment of the chronically ill child population that accounted for the majority of bed days and lost school days. Specifically, 72% of children with chronic conditions spent no days confined to bed in the previous year, and 59% had no school absences attributable to chronic illness. At the other end of the spectrum, 8% of children with chronic conditions spent 7 or more days confined to bed in the previous year and accounted for 74% of all bed days caused by chronic illness. Similarly, 12% of the population with chronic conditions had 7 or more school absence days and accounted for 73% of all school absences related to chronic health problems. Hence, a small segment of the chronically ill population disproportionately shoulders the burden of illness when that illness is measured in terms of bed days and school absences.

Impact of Childhood Chronic Conditions on Children's Use of Services

Use of medical services for children with chronic conditions is shown in Table 6. In 1988, 63% of all children with chronic conditions were reported by their parents to have used medications (excluding vitamins) prescribed or recommended by a doctor. In addition, 4% of children were hospitalized to treat their chronic health problems sometime during the year prior to the interview. Nationally, an estimated 690 000 children were hospitalized for a total of nearly 7.2 million days for treatment of chronic conditions.

Children averaged slightly under five physician contacts annually for the treatment of chronic conditions (excluding those occurring during inpatient hospital episodes). Nationally, chronically ill children were estimated to have made 92 million ambulatory physician contacts in 1988, excluding visits for routine preventive care and services obtained in treating acute conditions. Hence, these results illustrate the added health care burden of childhood chronic illness.

Like bed days and school absences, physician services were used at markedly varying rates by individual chronically ill children. Some children made very high use of those services whereas many had no physician contacts during the previous year. Specifically, 30% of children with chronic conditions had no physician services related to the care of chronic illnesses in 1988. In contrast, 10% had 10 or more contacts and accounted for 63% of all ambulatory physician services for chronic illness. Hence, a small segment of the chronically ill child population appears to account for the majority of ambulatory care services.

The Uneven Burden of Childhood Chronic Illness

The data presented above suggest that, although chronic conditions are quite common among children, a comparatively small number of children are severely affected by them. For example, only one in eight children with chronic conditions had any limitation on his or her usual activities. Similarly, most children experienced only occasional bother or no bother at all from their chronic conditions. Further analysis indicates that 66% of children with chronic conditions were never or only occasionally bothered by their conditions and had no limitations on their usual activities. These data suggest that two thirds of all children with chronic conditions are mildly affected by their conditions and experience little or no adverse effects on their activities.

At the opposite end of the severity spectrum are children who were bothered by their conditions often or all of the time *and* limited in their usual activities

TABLE 2—Prevalence of Specified Chronic Conditions among Children under 18 Years of Age, 1988

Condition	N	Cases per 1000	Std Error	Cases in 1000s
All children with chronic conditions	5332	307.6	6.8	19 556

[a]standard error exceeds 30% of estimate value.

by chronic illness. This severe group is much smaller, including only 5% of children with chronic conditions. In between these extremes are the remaining 29% of children with chronic conditions. This group includes children who experienced more than occasional bother or limitation of activity, but not both (see Figure 1). Expressed another way, 20% of U.S. children experienced mild chronic conditions, 9% experienced chronic conditions of moderate severity, and only 2% of children experienced severe chronic conditions in 1988.

Children in the severe group spent an average of 10 days in bed and missed 11 days from school annually. Despite their small numbers, they account for 27% of all bed days and 24% of all school absences related to chronic conditions. Their use of medical services was also extraordinary.

TABLE 4—Percent Distribution of Childhood Chronic Conditions by Frequency and Amount of Bother, 1988

Condition	Frequency of Bother			Amount of Bother		
	Never	Once in Awhile	Often or All the Time	Never	Very Little or Some	Great Deal
All conditions	24.7	53.0	22.3	24.7	50.1	25.2

[b]information on bed days and school absences was not obtained for these conditions.

Children in this group had an average of 16 physician contacts annually, and 16% were hospitalized during the previous year. Together they account for 19% of all physician contacts and 33% of all hospital days resulting from chronic conditions. In addition, 85% of children in this group received physician-recommended medications.

As one might expect, the diagnostic case mix differs substantially at each extreme of the severity spectrum. Children with mild chronic conditions were much more likely than children with severe chronic conditions to have respiratory allergies and repeated ear infections. In contrast, children in the severe group were more likely than children in the mild group to have musculoskeletal impairments, hearing and speech impairments, cerebral palsy, diabetes, asthma, epilepsy, and arthritis. In addition, children in the severe group had an average of 2.6 conditions, compared with an average of only 1.3 conditions per child in the mild group.

Discussion

In reviewing the NHIS results presented here, the reader should keep in mind that the results are based on household interviews, not on diagnostic tests or medical examinations. These results represent the mother's or other adult's *perception* of the child's health. Respondents are more likely to report conditions that have some impact on a child's activities.

Similarly, conditions associated with recent medical encounters are more likely to be accurately reported in household interviews. In contrast, conditions with little functional impact are often underreported, as are conditions that are associated with embarrassment or stigma.[19,20]

Although NCHS has undertaken validation studies, none of these studies has focused on children. Comparison of NHIS interview data from the early 1960s with information derived from medical records for *adults* suggests that chronic conditions, particularly those not causing significant disability, are generally underreported in household interviews. The most recent study of NHIS interviewing methodology found that between 35% and 45% of conditions found in medical records were unreported in household interviews whereas between 8% and 12% of conditions reported in interviews were not found on medical records. Conditions most likely to be underreported in household interviews include those related to the urinary and reproductive systems, mental illness, and cancer.[19,20] The results presented here for children contain at least one instance to suggest that misreporting may occur among respondents. Specifically, 18% of child diabetics were reported as unmedicated in the last year, indicating that either parents overreport diabetes or underreport use of medications.

With these limitations in mind, results from this investigation suggest that childhood chronic conditions are quite common in the United States. Using a broad definition of chronic illness, approximately 31% of all children under 18 years of age were classified as having chronic conditions in 1988. The overall prevalence of chronic conditions was similar for adolescents and younger children. Chronic conditions were reported more frequently for boys than for girls and for Whites than for Blacks. In fact, differences in prevalence were especially large for the two racial groups; however, whether these racial differences are attributable to reporting biases or underlying differences in health cannot be discerned from this data set.

Our results indicate that children with chronic conditions experience a substantial added burden of illness. In 1988, chronically ill children tallied 37 million bed days and 41 million school absence days attributable to chronic conditions. As previously noted, they also made 92 million physician contacts and accounted for over 7 million hospital days related to the treatment of chronic conditions. Using an average daily cost of $581 for hospital care[21] and $36 for intermediate-level visits for established pediatric patients (CPT 90060),[22] we estimate the cost of hospital and physician care related to childhood chronic conditions to be approximately $7.5 billion annually. This estimate may be somewhat inflated because physician contacts as defined in the questionnaire include consultations in person or by telephone. At the same time, however, this estimate does not include charges for nonphysician professional services, medications, supplies and equipment, and other specialized services used by chronically ill children.

Our results also indicate that the bur-

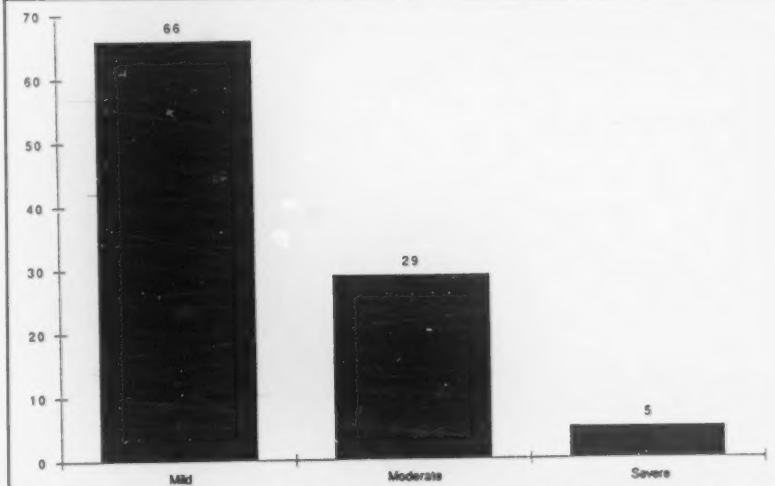

FIGURE 1—Percentage distribution of children with chronic conditions, by severity level, 1988.

den of chronic illness is not borne evenly by these children. Chronic conditions fall along a continuum that begins with those that have essentially no impact on the child and ends with those that affect the child and the family profoundly. Using this continuum approach, the 31% of US children with chronic conditions can be divided into three groups: 20% with mild conditions that result in little or no bother or activity limitations; 9% with conditions of moderate severity that result in some bother or limitation of activity, but not both; and 2% with severe conditions that cause frequent bother and limitation of activity.

In prior prevalence studies using other data sources, prevalence estimates for childhood chronic conditions have ranged from less than 5% to more than 30%. The overall prevalence estimate of 31% from the 1988 NHIS is clearly at the upper extreme of previous prevalence estimates whereas our 2% estimate for the prevalence of severe conditions is clearly at the lower extreme. This illustrates the sensitivity of prevalence estimates to the definition used.

Results from the NHIS clearly demonstrate the wide variability with which specific conditions affect the health of children. The impact of chronic conditions on a given child is influenced by their type, number, and severity. The impact is also determined by external factors, such as psychosocial support within the family, access to medical and other services, effectiveness of treatment and rehabilitative interventions, and acceptance by the community of children with chronic conditions. With a goal to diminish the impact of illness and prevent dysfunction in children, the variability in impact on health warrants further study to determine which external factors could be modified to improve health. □

APPENDIX A—Questions Used to Determine Impact of Childhood Conditions

1) During the past 12 months, did ____ (*condition/AIP*) cause ____ to miss any time from school?
2) How many days in the past 12 months did ____ miss all or part of the day?
3) During the past 12 months, did ____ (*condition/AIP*) cause ____ to stay in bed more than half of the day?
4) How many days in the past 12 months did ____ stay in bed more than half of the day?
5) During the past 12 months, about how many nights did ____ spend in the hospital because of (*condition/AIP*)?
6) During the past 12 months, about how many times did [___/anyone] see or talk to a medical doctor or assistant about this (*condition/AIP*)? (Do not count doctors seen while an overnight patient in a hospital.)
7) During the past 12 months, did this (*condition/AIP*) make it necessary for ____ to use any medicine, other than vitamins, that a doctor prescribed OR told ____ to take?
8) In the last 12 months, how often did [this condition/the conditions resulting from the (*AIP*)] cause ____ pain or discomfort or upset — all of the time, often, once in a while, or never?
9) When this condition did bother ____, was ____ bothered a great deal, some, or very little?

Note: AIP = accidents, injuries, or poisonings.

APPENDIX B—Categorization Scheme

Condition Category	Checklist Conditions Included
Impairments	
Musculoskeletal impairments	missing limbs, fingers, or toes[a]
	permanent impairment; stiffness or deformity of back or side, limbs, fingers, or toes[a]
Deafness and hearing loss	deafness or trouble hearing in one ear[a]
	deafness or trouble hearing in both ears[a]
Blindness and vision impairment	blindness in one eye[a]
	blindness in both eyes[a]
	crossed eyes[a]
	any other trouble seeing[a]
Speech defects	stammering or stuttering
	any other speech defect
Cerebral palsy	cerebral palsy[a]

Reductions in HIV Risk–Associated Sexual Behaviors among Black Male Adolescents: Effects of an AIDS Prevention Intervention

John B. Jemmott III, PhD, Loretta Sweet Jemmott, RN, PhD, and Geoffrey T. Fong, PhD

ABSTRACT

Background. The number of reported cases of acquired immune deficiency syndrome (AIDS) is increasing disproportionately among Blacks in the United States. The relatively high incidence of sexually transmitted diseases among Black adolescents suggests the need for AIDS prevention programs to reduce their risk of sexually transmitted human immunodeficiency virus (HIV) infection.

Methods. Black male adolescents (n = 157) were randomly assigned to receive an AIDS risk reduction intervention aimed at increasing AIDS-related knowledge and weakening problematic attitudes toward risky sexual behavior, or to receive a control intervention on career opportunities.

Results. The adolescents who received the AIDS intervention subsequently had greater AIDS knowledge, less favorable attitudes toward risky sexual behavior, and lower intentions to engage in such behavior than did those in the control condition. Follow-up data collected 3 months later revealed that the adolescents who had received the AIDS intervention reported fewer occasions of coitus, fewer coital partners, greater use of condoms, and a lower incidence of heterosexual anal intercourse than did the other adolescents.

Conclusions. These results suggest that interventions that increase knowledge about AIDS and change attitudes toward risky sexual behavior may have salutary effects on Black adolescents' risk of HIV infection. (*Am J Public Health.* 1992;82:372–377)

Introduction

Acquired immune deficiency syndrome (AIDS) has created a major health crisis. In the United States, over 179 000 cases of AIDS had been reported as of May 1991, with over 113 000 deaths attributed to the disease.[1] But these numbers represent only part of the problem. An estimated 1 million people have been infected by the human immunodeficiency virus (HIV), the cause of AIDS.[2,3] These people, too, are likely to develop AIDS. Although HIV can be transmitted perinatally from infected mothers to their newborns, the risk of infection is primarily associated with two kinds of behaviors: (1) the sharing of contaminated hypodermic needles and other drug paraphernalia and (2) the exchange of semen, blood, or vaginal fluids during sexual activities.[1] The most promising method of curtailing the spread of AIDS is to reduce the frequency of high-risk behaviors.

In this paper we report the results of a field experiment employing an intervention designed to reduce the frequency of HIV risk–associated sexual behaviors among inner-city Black male adolescents. Although most reported AIDS cases in the United States involve White homosexual and bisexual men, Blacks are, in fact, disproportionately burdened by AIDS. Only 12% of the nation's population is Black, yet 28% of AIDS patients are Black.[1] Adolescents represent 1% of all reported AIDS cases in the United States. But this statistic may underestimate the potential for HIV infection among adolescents. Adults in their 20s constitute 20% of all reported AIDS cases, and because several years typically elapse between the time a person is infected with HIV and the appearance of clinical signs sufficient to warrant a diagnosis of AIDS, many of these young adults may have acquired the infection as adolescents.[4]

Statistics on rates of sexually transmitted diseases (STDs) and unintended pregnancy suggest that adolescents engage in sexual activities that heighten risk of HIV infection.[5–11] Adolescents have higher rates of syphilis, gonorrhea, and pelvic inflammatory disease than do all other age groups. Inner-city Black adolescents, however, are particularly at risk: STDs are two to three times more common in inner-city populations, and the adolescent pregnancy rate is nearly twice as high among Blacks as among Whites. The prevalence of intravenous drug use in the inner city also heightens the risk of HIV infection for Black adolescent residents. Although the adolescents themselves may not use intravenous drugs—indeed, some data[12] indicate that intravenous drug use among adolescents is rare—they may have sexual relationships with intravenous drug users or with individuals who have had sex with such potentially infected persons.

Despite the potential risk of sexually transmitted HIV infection among inner-city Black adolescents, there is a dearth of intervention studies on behavior change in

This paper was submitted to the Journal February 20, 1991, and accepted with revisions August 22, 1991.

this population. More broadly, research into adolescents' sexual behavior, for the most part, has been conducted on female adolescents.[13] Yet it is also important to understand the dynamics of male adolescents' sexual behavior. Male adolescents are more likely to initiate sexual activities with their partners,[13,14–16] and the male's use of a condom is the best method to reduce the risk of contracting or spreading an STD during sexual activities.

Recent studies provide initial experimental evidence that AIDS prevention interventions emphasizing attitudes, knowledge, and skill-building can increase condom procurement among Black male adult STD patients[17] and self-reported condom use among White male homosexuals.[18] In an AIDS intervention study[19] of Black and Hispanic adolescents, those in the intervention conditions, compared with those not receiving an intervention, showed increased ratings of the value of AIDS education and reduced approval of intravenous drug use 1 month after the intervention. DiClemente and colleagues[20] tested an AIDS education intervention on classes within middle and high schools in San Francisco and found that, compared with control classes, those that received the AIDS instruction had greater AIDS knowledge and less fear of being infected by classmates who have the disease. DiClemente et al.[20] urged behavioral assessments in future intervention studies on adolescents.

In the present study we examined whether Black male adolescents who were randomly assigned to an AIDS risk reduction intervention would have greater knowledge and less positive attitudes and intentions regarding risky sexual behavior than would those assigned to a control intervention on career opportunities. Most important, we also examined whether risky sexual behaviors would decline in the intervention condition, relative to the control condition, during the 3 months after the intervention.

Methods

Study Sample

The participants were 157 Black male adolescents (mean age = 14.64 years, SD = 1.66) from Philadelphia, Pa, who were recruited from among outpatients at a medical clinic in West Philadelphia (44%); students attending the 10th, 11th, and 12th grade assemblies at a local high school (32%); and adolescents at a local YMCA (24%). (The results do not differ as a function how subjects were recruited.) About 97% of the participants were currently enrolled in school. The mean number of years of education of their mothers, as reported by participants, was 13.82 (SD = 3.17). Few participants (4.5%) reported ever sharing needles or ever having receptive anal intercourse (2.3%), or having sexual relationships with males exclusively (1.6%) or with both males and females (0.8%). Their chief HIV risk was from heterosexual activities. About 33.9% reported having more than one coital partner in the previous 3 months, and 12.8% of the respondents indicated that they had had heterosexual anal intercourse during that period. About 20.9% of the respondents who had had coitus in the previous 3 months reported that they never used condoms during those experiences, and only 30.2% reported always using condoms. The adolescents were offered $40 for participating: $15 for taking part in the intervention and $25 for attending the 3-month follow-up. Of the original participants, 150 completed the 3-month follow-up questionnaire, for a return rate of 96%. The return rate was not different between experimental conditions.

Procedure

The study was approved by the human subjects committee of Princeton University. Adolescents and parents signed separate consent forms. They were given descriptions of the study that took into account the fact that the adolescents would be randomly assigned to an AIDS risk reduction intervention or to a career-opportunities intervention. The study was described as a risk reduction project, designed "to understand Black male youths' behaviors that may create risks such as unemployment, truancy, teenage pregnancy, and sexually transmitted diseases, especially AIDS, and to find ways to teach Black male youth how to reduce these risks."

The intervention session was held at a local school on Saturday, October 15, 1988. That morning, the participants completed preintervention questionnaires, which took about 90 minutes. Immediately before completing the questionnaires, the participants signed an agreement indicating that they understood that it was important to answer the questions carefully and honestly, that their answers would be confidential, and that their names would not be put on their questionnaires. The participants also signed such agreements before completing postintervention and follow-up questionnaires. Research indicates that this procedure increases the accuracy of self-reports. While the participants completed the preintervention questionnaires, they were stratified by age and randomly assigned within age to either the AIDS condition or the career-opportunities condition and to one of 27 small groups (14 in the AIDS condition and 13 in the control condition) led by a trained male or female facilitator. A total of 85 adolescents were assigned to the AIDS condition, and 72 were assigned to the control condition. The sample sizes are smaller in some analyses because of attrition or because subjects gave no response to the question.

AIDS risk-reduction condition. Participants in the AIDS risk reduction condition received a 5-hour intervention designed to increase their knowledge of AIDS and STDs and to weaken problematic attitudes toward risky sexual behaviors. The intervention included information about risks associated with intravenous drug use and specific sexual activities. Videotapes, games, exercises, and other culturally and developmentally appropriate materials were used to reinforce learning and to encourage active participation. All materials had been extensively pilot tested and were selected not only to provide accurate information, but to do so in ways that would be interesting to inner-city Black male adolescents. For example, one video, "The Subject is AIDS," was narrated by a Black woman and had a multiethnic cast. In one game, "AIDS Basketball,"[21] participants in small-group sessions were divided into teams that earned points for correctly answering factual questions on AIDS. In one exercise, "Uncle Bill's Advice Column,"[21] pairs of adolescents wrote a response to a letter to Uncle Bill about AIDS or risky behavior and then read it to the rest of the group for discussion. A condom exercise focused on the correct use of condoms. The participants also engaged in role-playing situations depicting potential problems in trying to implement safer sex practices, including abstinence. A more detailed description of the intervention is available from the authors.

Career-opportunities condition. An important concern in designing this experiment was to control for Hawthorne effects to reduce the likelihood that effects of the AIDS intervention could be attributed to nonspecific features, including group interaction and special attention. A waiting-list or no-treatment control condition would not control for these confounding variables and consequently was seen

as undesirable. In addition, for ethical and methodological reasons, every effort was made to ensure that the experiences of control participants were as valuable and enjoyable as those of experimental participants.[22] Accordingly, participants in the control condition received an intervention concerning career planning and opportunities. Structurally similar to the AIDS intervention, it also lasted 5 hours and used videotapes, small-group discussions, exercises, and games. The participants viewed the film "Career and You." In one game, "The Career Game," participants in small groups were divided into teams that earned points for correctly answering questions about careers. They participated in a value-awareness exercise, and they did a career analysis.

After the interventions, all participants completed the postintervention questionnaires. This took about an hour. To reduce the effects of demand characteristics, the questionnaires were administered by research assistants, not by the facilitators.

Facilitators

The facilitators were 27 Black adults (11 women and 16 men) with a mean age of 36.2 years (SD = 6.8). The AIDS facilitators had backgrounds in human sexuality education, mental health counseling, AIDS education, nursing, or social work. The career-opportunities facilitators had backgrounds in education, career guidance, or business. All facilitators had at least a 4-year college degree. A majority had experience with small-group facilitation.

One week before the intervention, the facilitators received 6 hours of training. AIDS and careers facilitators were trained at the same time, but in separate groups. By discussing potential problems and issues as a group, the facilitators were able to fashion common responses. The training emphasized that all facilitators of the same intervention must implement it in the same way so as to reduce facilitator effects.

Measures

Risky sexual behavior during the previous 3 months. On the preintervention and follow-up questionnaires, the participants answered a series of questions about their sexual practices in the previous 3 months, including coitus, multiple sexual partners, condom use, and heterosexual anal intercourse. At each assessment, participants' responses to the individual items were converted to z scores and then averaged to form a scale on which higher scores indicated higher incidence of risky sexual behavior. Coefficient α for the scale was .67 at preintervention and .72 at follow-up.

Intentions and attitudes regarding risky sexual behavior in the next 3 months. The theory of reasoned action and a growing empirical literature suggest that attitudes and intentions are related to behavior, including HIV risk–associated sexual behavior.[23–27] The participants' attitudes and intentions regarding engaging in the aforementioned sexual practices in the next 3 months were measured at preintervention, immediately postintervention, and at the 3-month follow-up. To measure intentions, participants were asked to rate the likelihood that they would engage in each behavior in the next 3 months on a scale from "extremely unlikely" (1) to "extremely likely" (7). At each time point, the ratings were averaged to form scales on which higher numbers indicated stronger intentions to engage in risky sexual behavior in the next 3 months. Coefficient α was .68 at preintervention, .72 at postintervention, and .70 at follow-up. To measure attitudes, participants were asked to rate their attitudes toward engaging in each behavior in the next 3 months on a scale from "extremely negative" (1) to "extremely positive" (7). At each time point, the ratings were averaged to form scales on which higher numbers indicated more favorable attitudes toward engaging in risky sexual behavior in the next 3 months. Coefficient α was .63 at preintervention, .68 at postintervention, and .63 at follow-up.

AIDS and STD knowledge. Participants answered factual true-false questions regarding AIDS and STDs. Thirty items concerned AIDS and were taken from scales previously used in research on adolescents by DiClemente et al.[20,28] Thirty additional items concerned information about either AIDS or STDs in general that is not tapped by the DiClemente measures. To ensure the content validity of the scale, six AIDS experts—scientists and clinicians involved in AIDS-related research, patient care, or education—rated the information in each item on a 3-point scale from "unimportant" (0) to "important" (1) to "essential" (2) for laypersons to know. Eighteen items were seen as essential (mean ratings = 2.0) by every judge, and 39 items had mean ratings in the important to essential range (mean ratings $\geq$ 1.00). Three items the judges considered either ambiguous or unimportant were deleted. The number correct out of 57 was calculated from the preintervention, postintervention, and follow-up questionnaires. Coefficient α was .73, .89, and .82, respectively.

Other measures. On the postintervention questionnaire, the participants answered a series of questions about their perceptions of the intervention activities. The facilitators completed a questionnaire regarding their impressions of the experience of the adolescents in their small groups and their success at implementing the intervention. The Marlowe-Crowne Social Desirability Scale[29] was used to measure the tendency of participants to describe themselves in favorable, socially desirable terms.

Results

Intervention Integrity

Before considering effects of the AIDS intervention on knowledge, attitudes, intentions, and behavior, it is important to establish that the participants in the two conditions were equally involved in their interventions and found them to be valuable and enjoyable. There were no differences between conditions in the participants' ratings of their liking for the intervention, their learning from the activities, whether the intervention would help them in the future, their general emotional reactions toward the intervention, or their participation level. The only significant difference between the groups was that those in the AIDS condition would be more likely to recommend the project to other teenagers than would those in the careers condition—mean ratings of 4.18 vs 3.78 on a 5-point scale, F (1, 152) = 4.43, $P < .04$. The facilitators' ratings of their small groups were consistent with the participants' self-ratings: They revealed a high degree of attentiveness and interest, with no differences between conditions. In addition, there was evidence that the facilitators had been successful in presenting the interventions in the same way. Analyses on knowledge, attitudes, intentions, and behavior revealed no differences that could be attributed to the particular small group in which the adolescents participated, independent of experimental condition.

Knowledge, Attitudes, and Intentions

The data were analyzed with Condition × Gender of Facilitator analyses of covariance,[30] controlling for preintervention measures of the relevant crite-

rion. Table 1 contains the adjusted postintervention means. Immediately after the intervention, participants in the AIDS condition had greater knowledge about AIDS, F (1, 151) = 19.58, $P < .0001$, expressed less favorable attitudes toward risky sexual behaviors, F (1, 150) = 8.42, $P < .004$, and reported weaker intentions to engage in such behavior than did their counterparts in the career-opportunities condition, F (1, 150) = 17.45, $P < .0001$. The Condition × Gender of Facilitator interaction on knowledge was significant, F (1, 151) = 4.26, $P < .04$, indicating that the degree of increase in knowledge caused by the AIDS intervention was greater with male facilitators than with female facilitators.

Three-month follow-up. Three months after the intervention, participants in the AIDS condition still scored higher on AIDS knowledge, F (1, 147) = 9.46, $P < .003$, and reported weaker intentions to engage in risky sexual behavior in the next 3 months, F (1, 144) = 7.58, $P < .007$, than did those in the career-opportunities condition. Table 2 contains the adjusted means. There was a nonsignificant trend toward less favorable attitudes regarding risky sexual behavior among those in the AIDS condition than among those in the control condition, F (1, 144) = 2.82, $P < .10$. However, a significant Condition × Gender of Facilitator interaction, F (1, 144) = 8.91, $P < .003$, indicated that the effect of the AIDS intervention on lowering attitudes was greater with female facilitators than with male facilitators.

Risky Sexual Behavior

As Table 2 shows, when preintervention reports of risky sexual behavior are controlled for, participants in the AIDS condition reported engaging in less risky sexual behavior in the 3 months following the intervention than did participants in the career-opportunities condition, F (1, 135) = 6.48, $P < .01$. The Condition × Gender of Facilitator interaction was significant, F (1, 135) = 4.19, $P < .04$, indicating that the reduction in risky sexual behavior caused by the AIDS intervention was greater with female facilitators than with male facilitators.

Table 3 shows that the effects of the intervention were fairly consistent across different sexual behaviors. Although adolescents in the AIDS condition were not significantly ($P < .10$) more likely than those in the career-opportunities condition to practice complete abstinence in the 3 months postintervention, they did report having coitus on fewer days, with fewer women, and with fewer women who were involved in sexual relationships with other men. Subjects in the AIDS condition also reported fewer occasions of coitus without a condom and were less likely to report having anal intercourse with a woman in the 3 months postintervention than were the other adolescents. Condition × Gender of Facilitator interactions of the same form as on the aggregate risky behavior index were statistically significant on number of days on which the participants engaged in coitus, number of days on which the participants had coitus without using a condom, and experience with heterosexual anal intercourse in the past 3 months.

TABLE 1—Adjusted[a] Postintervention Means, by Experimental Condition

Variable	AIDS Prevention Condition	Control Condition	Difference	95% CI of Difference
Knowledge	46.22 (85)	40.37 (71)	5.85	3.23, 8.48
Attitudes	3.02 (83)	3.48 (72)	−.46	−.77, −.15
Intentions	2.83 (83)	3.40 (72)	−.57	−.84, −.30

Note. Numbers of respondents are shown in parentheses. CI = confidence interval. Higher numbers indicate greater AIDS knowledge, more positive attitudes toward behaviors that increase risk of sexually transmitted HIV infection, and stronger intentions to engage in such behaviors.
[a] For each variable, the preintervention measure is partialled out of the postintervention measure.

TABLE 2—Adjusted[a] 3-Month Follow-up Means by Experimental Condition

Variable	AIDS Prevention Condition	Control Condition	Difference	95% CI of Difference
Knowledge	47.20 (83)	44.40 (67)	2.8	.72, 4.88
Attitudes	3.13 (82)	3.38 (67)	−.25	−.54, .04
Intentions	2.87 (82)	3.30 (67)	−.43	−.74, −.12
Risky behavior	−.12 (76)	.24 (62)	−.36	−.64, −.08

Note. Numbers of respondents are shown in parentheses. CI = confidence interval. Higher numbers indicate greater AIDS knowledge, more positive attitudes toward behaviors that increase risk of sexually transmitted HIV infection, stronger intentions to engage in such risky behaviors, and more reports of risky sexual behavior.
[a] For each variable, the preintervention measure is partialled out of the 3-month follow-up measure.

Social Desirability Bias

Marlowe-Crowne Social Desirability Scale scores were unrelated to preintervention self-reports, 3-month follow-up self-reports, or amount of change in self-reports of risky sexual behavior. In addition, the scores were unrelated to preintervention, postintervention, or follow-up intentions and attitudes or to changes in these variables.

Discussion

Given the widely recognized potential risk of sexually transmitted HIV among inner-city Black adolescents, the results of the present experiment are encouraging. They suggest that interventions that increase knowledge about AIDS and change attitudes toward risky sexual behavior may have salutary effects on Black adolescents' risk of HIV infection. Compared with their counterparts in the control condition, the inner-city Black male adolescents who were randomly assigned to an AIDS intervention subsequently had lower intentions of engaging in sexual behaviors that would increase their risk of contracting or spreading HIV infection. These adolescents also had less favorable attitudes toward risky sexual behaviors and greater AIDS knowledge. Analyses on data from the 3-month follow-up revealed that the adolescents who received the AIDS intervention also reported engaging in less risky sexual behavior following the intervention than did those who received the control intervention. Moreover, the effects of the intervention on intentions regarding risky sex-

TABLE 3—Adjusted[a] Means for Specific Sexual Behaviors, by Experimental Condition

Variable	AIDS Prevention Condition	Control Condition	Difference	95% CI of Difference
Coitus[b]	.48 (62)	.60 (53)	−.12	−.27, 0.3
No. days respondent had coitus	2.15 (53)	5.48 (47)	−3.32	−5.78, −.89
No. coital partners	.85 (63)	1.79 (52)	−.93	−1.53, −.33

[c] Frequency of condom use was rated on a 5-point Likert-type scale from 1 = "never" to 5 = "always."

ual behavior and AIDS-related knowledge were sustained over the 3 months. The effects on attitudes observed immediately postintervention were evident at the follow-up among participants who had a female facilitator.

These results cannot be explained as a simple result of the special attention received by the adolescents in the AIDS intervention condition. The two interventions were matched in length and involved similar kinds of activities. Moreover, the participants' evaluations of their experiences were quite similar across the interventions. Although career-opportunities subjects did not learn about AIDS, they did gain knowledge that would be valuable to them in the future, given the high unemployment among inner-city Black adolescents.

By its very nature, risky sexual behavior is private behavior and consequently must be assessed using self-report measures, which may be biased.[31] We employed several techniques to make it less likely that the subjects would minimize or exaggerate reports of their sexual experiences: (1) code numbers rather than names were used on the questionnaires, (2) facilitators were not involved in any way in the administration of questionnaires, (3) the importance of responding honestly was emphasized, and (4) participants were assured that their responses would be kept confidential. Furthermore, if concern about how they would be viewed by others influenced respondents' reports of their sexual behavior, those whose need for social approval was stronger[29] might have differed from the other adolescents in self-reported risky sexual behavior or in the change in their reports after the AIDS intervention. Responses, however, were unrelated to social desirability bias. Nevertheless, because it is difficult to validate self-reported sexual behavior,[31] interpretations of the present findings should take into consideration the possibility that the participants' self-reports might have been inaccurate.

It might be argued that the gender of facilitators and group members should be matched to enhance an intervention's effectiveness. Consonant with this argument, the AIDS intervention caused greater increases in postintervention AIDS knowledge when the facilitator was male than when the facilitator was female. But this advantage of male facilitators was not evident on postintervention attitudes or intentions, and it vanished at follow-up. In fact, 3-month follow-up data revealed that the AIDS intervention caused less self-reported risky behavior and less positive attitudes toward such behavior when the facilitator was female than when the facilitator was male. These results provide scant support for the view that matching the gender of facilitator and intervention recipient enhances the effectiveness of AIDS interventions with Black male adolescents.

One common argument against AIDS education programs for adolescents and children has been that exposing them to information about sex will encourage them to engage in sexual activity. Our data, however, provide some evidence that the opposite may be true. Adolescents who received the AIDS intervention were *less* likely to engage in sexual activity, and those who did were more likely to engage in safer sexual activity. Thus, the common fear that providing adolescents with information about AIDS will result in greater sexual activity is perhaps simply a fear.

The present study focused on sexual behaviors that heighten risk of HIV infection. However, the overwhelming majority of the subjects did not report any homosexual or bisexual experiences. Sharing needles and other intravenous drug use paraphernalia would also increase risk of HIV infection, but few of these subjects reported engaging in such behavior. The important question of whether interventions of the type used in the present study would be effective with Black male adolescents who engage in homosexual or bisexual activities or who use intravenous drugs will have to be addressed in future studies. More broadly, research on strategies to change HIV risk–associated behavior in diverse populations is still in its infancy. We are optimistic, however, that by conducting research along these lines, it may be possible to curb the spread of AIDS. □

Birth Weight and Perinatal Mortality: The Effect of Gestational Age

ABSTRACT

Background. The strong association between birth weight and perinatal mortality is due both to gestational age and to factors unrelated to gestational age. Conventional analysis obscures these separate contributions to perinatal mortality, and overemphasizes the role of birth weight. An alternative approach is used here to separate gestational age from other factors.

Methods. Data are from 400 000 singleton births in the Norwegian Medical Birth Registry. The method of Wilcox and Russell is used to distinguish the contributions to perinatal mortality made by gestational age and by relative birth weight at each gestational age.

Results. Gestational age is a powerful predictor of birth weight and perinatal survival. After these effects of gestational age are controlled for, relative birth weight retains a strong association with survival.

Conclusions. Current public health policies in the United States emphasize the prevention of low birth weight. The present analysis suggests that the prevention of early delivery would benefit babies of all birth weights. (*Am J Public Health.* 1992;82:378–382)

Introduction

Birth weight is the single strongest predictor of infant survival. However, its position in the causal pathway is unclear. One determinant of birth weight is gestational age: as the fetus matures, it grows. Some of the association of weight with survival presumably reflects this maturation. There is additional variability in weight that is unexplained by gestational age. This second type of birth weight variability is also strongly related to infant survival, but by biological mechanisms less well understood. The purpose of this paper is to separate mortality as related to gestational age from mortality as related to relative birth weight within fixed gestational age. In the process of such a separation, factors related to gestational age can be separated from other factors that contribute to perinatal mortality. This produces a picture of mortality that is different from the traditional weight-versus-age multivariate approach, a picture which may better reflect the underlying causal pathways.

Methods

Data are from the Medical Birth Registry of Norway, which includes all live births and fetal deaths after 16 weeks of gestation registered in Norway since 1967. We selected all singleton first births through 1984 with gestational ages of 28 or more weeks, totaling 413 051. Birth weights were grouped into 100-g categories, and gestational ages were grouped by completed weeks since last menstrual period. Birth weight data were missing for 0.2% of births and gestational age was missing for an additional 4.3%. Those births were excluded, leaving 394 386 births (Table 1). We defined perinatal mortality as fetal deaths plus deaths in the first week of life. Total perinatal mortality in this study group was 12.9 per thousand.

Our method of analysis adjusts for birth weight with the modified form of direct standardization suggested by Wilcox and Russell.[1,2] The modification is first to adjust all birth weights to a *z*-score scale. (A *z* score expresses birth weight in standard-deviation units relative to mean weight.) This *z* scale is based on the underlying Gaussian distribution of births in each group being compared. Standardization is carried out on the *z* scale of birth weight rather than on a scale of absolute birth weight. Such an approach allows the comparison of mortality for babies of the same *relative* weight (that is, relative to the Gaussian distribution of weight for the particular group), rather than for babies of the same absolute weight. When applied to an analysis of gestational age, this method identifies babies that are relatively small or large for their gestational age and compares them with babies of the same relative size at other gestational ages.

We estimate the *z* scale by fitting a Gaussian curve to the birth weight distri-

Editor's Note. See related Editorial by Kiely and Susser on page 343 of this issue.

bution within each gestational age stratum. Figure 1 shows the distribution of birth weights in each stratum. Birth weight distributions between 38 and 46 weeks are almost exactly Gaussian. Below 38 weeks, two systematic deviations from the Gaussian emerge. First, as gestational age decreases there are increasing numbers of small babies in the lower tail of the distribution, outside the Gaussian. Many of these are presumably pathological conceptuses, including macerated stillbirths who stopped growing some time before delivery. (At 28 to 31 weeks, the distribution in the lower tail is obscured by the grouping of births less than 1000 g.)

Second, there is an increasing number of relatively heavy births as gestational age decreases. This pattern has been frequently observed and is attributed to errors in measurement of gestational age.[3,4] Gestational age defined by last menstrual period can be in error for at least two physiologic reasons: the estimated gestation length can be too short when bleeding in early pregnancy is mistaken for the last menstrual period, or too long when conception follows an extended follicular phase. The excess of heavier babies at early gestational ages is thought to represent babies whose recorded age is shorter than their true gestational age, and who therefore actually belong in one of the heavier distributions occurring at later gestations. There is presumably some misclassification of gestational age in every stratum, but the unequal distribution of births among the strata makes misclassification more apparent in some strata than in others. A small rate of misclassification among the large numbers of births around term would produce a considerable excess of heavy babies among the small numbers born into the preterm groups.

Deviations from the Gaussian distribution cause some difficulties in estimating parameters of the underlying Gaussian. A FORTRAN program has been developed to estimate these parameters in the presence of excess small births.[5,6] (This program is available upon request.) The FORTRAN procedure was suitable for most gestational-age strata, but did not work well at gestations of less than 38 weeks owing to the excess of heavy births. In those cases we have fit a Gaussian curve more approximately to the modal region of each distribution and extrapolated a standard deviation from later strata (Figure 1). Parameters of the Gaussian distribution for each gestational age stratum are shown in Table 2.

TABLE 1—Distribution of Births and Deaths by Gestational Age, with Gestational-age-Specific Relative Risks for Perinatal Death (Relative to Births at 40 weeks) before and after Adjustment for Birth weight

Gestational Age (weeks)	All Births	Perinatal Deaths	Perinatal Mortality[a]	Relative Risk[b]	Birth-weight-adjusted Relative Risk
28–31	2834	1034	364.9	85	91

[b]Relative to mortality at 40 weeks.

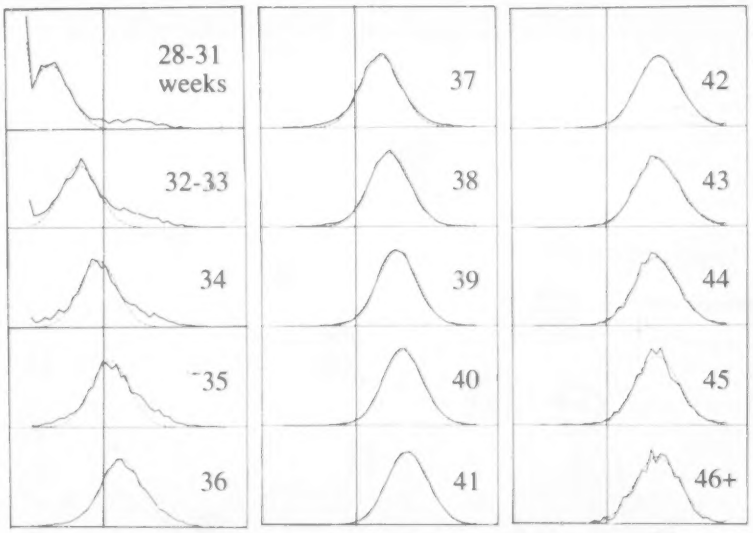

FIGURE 1—Frequency distributions of birth weight stratified by gestational age (solid curves), with underlying Gaussian distributions (dashed curves). A line at 2500 g is provided for reference.

Once parameters for each Gaussian were in hand, the mean and standard deviation for each gestational-age group were used to rescale birth weight to a z score. Weight-specific mortality rates for each group were also adjusted to the z scale in preparation for direct standardization. The choice of a distribution for the standard is not crucial. In general, the standard distribution should be similar to the actual distributions in the groups being analyzed. We chose a Gaussian distribution as our standard because it meets this criterion (Figure 1), but other distributions produce similar results. This standard distribution was applied to the weight-specific mortality rates for each gestational-age stratum. The risk of mortality for each gestational age was then expressed as a relative risk, with babies born at 40 weeks as the reference group.

TABLE 2—Gestation-specific Parameters of the Gaussian Birth Weight Distribution

Gestational Age weeks	Parameters of the Underlying Gaussian	
	Mean, g	SD, g
28–31	1425	400
32–33	2010	400

42	3645	460
43	3605	470
44	3560	470
45	3560	465
46+	3585	480

Results

A strong gradient of risk was observed across gestational age after birth weights were adjusted to a *z* scale. Babies at the earliest stratum had a relative risk of 91 (Table 1). Relative risks calculated by this method are similar to those for gestational age unadjusted for birth weight.

The same results are presented graphically in Figures 2 and 3. First, weight-specific mortality rates for nine selected gestational-age strata are shown before adjustment to a *z* scale. (Mortality rates have been smoothed by grouping weight into 300-g categories.) These curves have the usual features of weight-specific mortality: rates are highest at the lowest birth weights, fall rapidly as birth weights increase, and then rise slightly at the highest birth weights.[7]

At lower weights, mortality rates are similar across the various gestational age groups, whereas at higher weights the rates tend to diverge. This pattern changes with adjustment of the birth weight scale. Figure 3 shows the identical mortality curves after birth weight has been converted to the *z* scale. Curves that formerly converged at the lower weights are now separate and roughly parallel over the whole range of birth weights. The distance between any two curves in Figure 3 represents the log of the relative risk associated with the corresponding difference in gestational age. The adjusted relative risks in Table 1 summarize the differences between the lowest mortality curve (at 40 weeks) and each of the other mortality curves in Figure 3.

Figure 4 inverts the display to show perinatal mortality risk by gestational age for babies at given *relative* birth weights. Thus, the top curve shows mortality rates for that high-risk group of babies who are four standard deviations below the mean weight for their gestational age. The next-to-bottom curve shows the mortality experience of babies who are at the mean weight for their gestational age. Within each birth weight group there is a strong gradient of mortality risk with gestational age, with the lowest risk occurring at 40 weeks.

Discussion

Growth is a natural part of the gestational maturation of the fetus. When we refer here to "gestational age" we mean not merely age itself but the tightly correlated phenomena of growth and maturation. Gestational age is a major contributor to birth weight, but it is only one of several contributors. There is another set of factors, less well understood, that produces variation in birth weight within each stratum of gestational age. Some authors attribute this variation entirely to the quality of fetal growth. We regard this interpretation as potentially misleading[8] and prefer the more neutral description "relative weight at each gestational age." This expression is a generalized form of the clinical terms "small for gestational age" or "large for gestational age."

The usual analysis of birth weight and gestational age finds that most of the association with mortality is through birth weight. This was well illustrated by Susser, Marolla, and Fleiss, who reported that when gestational age and weight are analyzed simultaneously, birth weight accounts for 90% of the variance of perinatal mortality, whereas gestational age accounts for barely 5%.[9]

Such conclusions are based on data in the form shown here in Figure 2. Arranged in this way, the mortality curves at different gestational ages are nearly indistinguishable across the lowest birth weights (where rates are highest). For example, babies at 2250 g have a similar risk of death whether their gestational age is 35 or 37 or 40 weeks (Figure 2). Although this analysis may seem to isolate the separate effects of gestational age and birth weight, it does not uncover the causal pathway. Susser and his colleagues were careful not to draw such conclusions, but these data have suggested to some that birth weight is fundamentally more important to survival than gestational age.[10]

If we compare babies of the same *relative* weight at each gestational age, a different picture emerges. Figure 3 shows mortality rates for babies at various relative weights (expressed as standard deviations from the mean at each gestational age). In effect, this compares all small-for-gestational-age babies (or all average-weight babies, or all large-for-gestational-age babies) across different gestational ages. Actual comparison of small-for-gestational-age mortality risks across gestational-age strata shows the same strong effect of gestational age on mortality.[11]

Babies of 2250 g have similar mortality risk regardless of gestational age. But these babies differ considerably in their relative size (Figure 3). At 35 weeks, a baby of 2250 g is about one standard de-

FIGURE 2—Weight-specific mortality rates for nine representative strata of gestational age.

viation below the Gaussian mean weight. At 37 weeks, a baby of that weight is about two standard deviations below the mean, and at 40 weeks it is about three standard deviations below the mean. (See circled points on Figure 3). The similar mortality risk of these three babies is the result of two opposing trends: relative size is worse, and gestational age is better.

The usual analytic methods, in which 2250-g babies are compared at different gestational ages, do not take into account the full benefit that would accrue to a preterm baby from extended gestation. Any strategy of prevention or intervention implicitly assumes that extended gestation is accompanied by fetal growth, that is, that a fetus' *relative* weight stays roughly the same as gestation advances. To measure the advantage of longer gestation, the survival of a 2250-g baby at 35 weeks should be compared with the survival of a baby who has grown at the expected rate in the interim. Such a comparison is accomplished by the adjustment to a relative birth weight scale. In Figures 3 and 4 the effects of relative size and gestational age are separated, showing the relationship of each to survival.

The parameters estimated for the Gaussian distributions of weight at the earlier gestational ages are subject to judgment. Even so, the uncertainty regarding parameters used for z scales is not crucial to the conclusion. As an illustration, births at 35 weeks had a relative risk of 12, compared with births at 40 weeks. If we vary the mean of the Gaussian distribution at 35 weeks by plus or minus 50 g, or the standard deviation by plus or minus 25 g, the relative risk for that stratum ranges from 11 to 13. Such a fluctuation is minor in comparison with the relative risk of 21 for 1 week earlier, or the relative risk of 6.4 for 1 week later.

More generally, the result here does not depend on a Gaussian distribution as the standard. Even a rectangular distribution produces nearly the same set of relative risks. This is because the mortality curves shown in Figure 3 are roughly parallel on the log scale, making the ratio of rates between any two gestational age groups approximately constant across the spectrum of birth weight. To the degree those ratios are constant, the choice of a distribution for standardization is inconsequential.[12] The central requirement for the method of standardization used here is that all data be compared on a scale of relative birth weight (the z scale), rather than on a scale of absolute birth weight.

The present analysis highlights the importance of gestational age, and at the same time confirms a strong link between birth weight and perinatal mortality at each fixed gestational age. In his commentary on Wilcox and Russell's general approach, Peters stated that it was not possible to assess the "ultimate validity" of their model without considering gestational age.[13] Figure 3 shows that the relation between birth weight and perinatal mortality is not altered by stratifying on gestational age.

Gestational maturity has been understood for centuries to be important to infant survival. Still, gestational age tends to be slighted in contemporary US research.

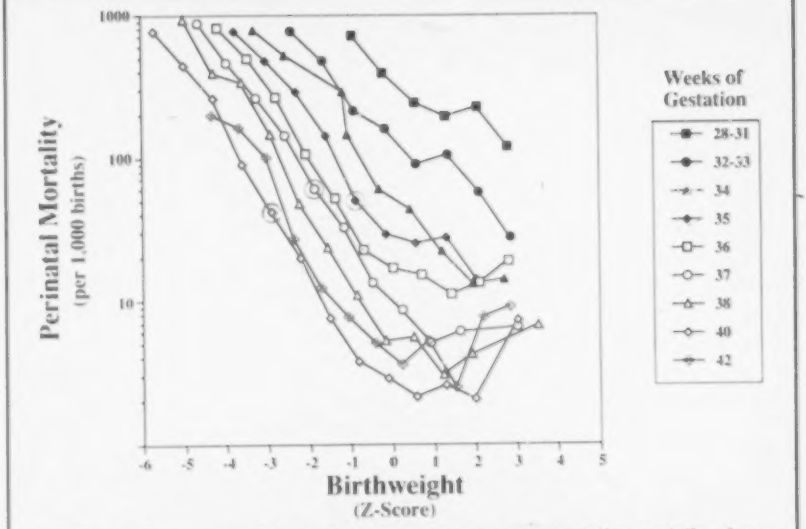

FIGURE 3—Z-score–specific mortality rates for nine representative gestational-age strata of births. (Circled points show mortality for 2250-g babies at different gestational ages. See text for discussion.)

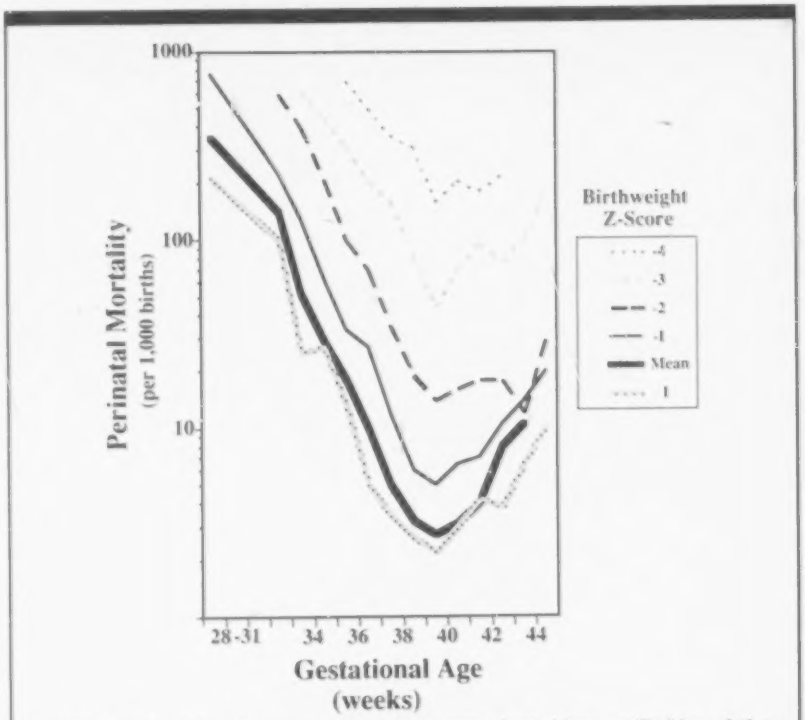

FIGURE 4—Gestational-age–specific mortality rates for babies stratified by relative size (in standard deviations from the Gaussian mean).

This neglect may be due to a lack of clarity about the role of gestational age in the causal pathway. We have shown that there are two strong and separable factors affecting perinatal survival. One is gestational age, and the other is relative birth weight at any given gestational age. A baby can benefit as much from an increase in gestational age as from an increase in its weight relative to the weights of others at the same gestational age. This benefit of additional weeks of gestational age tends to be obscured by the customary multivariate methods of "controlling" for birth weight. There is a fallacy in inferring causality from a highly predictive relationship in a statistical model. The dominance of birth weight when the ordinary analytic methods are used may have contributed to the current emphasis on low birth weight as a public health problem.[14] Interventions aimed at increasing the size of babies may have little effect on perinatal mortality. Preterm delivery appears to be as worthy a target for public health intervention as low birth weight, and may be more amenable to change. □

Estimation of the Break-Even Point for Smoking Cessation Programs in Pregnancy

ABSTRACT

Background. Successful programs to help pregnant women quit smoking have been developed and evaluated, but formal smoking cessation programs are not a part of care at most prenatal sites. The cost of such programs may be an issue. Considering the costs of adverse maternal and infant outcomes resulting from smoking, we estimated there would be an amount of money a prenatal program could invest in smoking cessation and still "break even" economically.

Methods. A model was developed and published data, along with 1989 hospital charge data, were used to arrive at a break-even point for smoking cessation programs in pregnancy.

Results. Using overall United States data, we arrived at a break-even cost of $32 per pregnant woman. When these data were varied to fit specific US populations, the break-even costs varied from $10 to $237, with the incidence of preterm low birth weight having the most impact on the cost.

Conclusions. It may be advisable to invest greater amounts of money in a prenatal smoking cessation program for some populations. However, for every population there is an amount that can be invested while still breaking even. (*Am J Public Health.* 1992;82:383–390)

Introduction

Cigarette smoking has been linked with adverse pregnancy outcome since at least the 1940s[1,2] and is the most important cause of low birth weight (LBW) in developed countries.[3] However, smoking cessation during the first trimester leads to infant outcomes similar to those for nonsmokers,[4] suggesting that smoking cessation programs during early pregnancy can alter pregnancy outcomes.

Although successful programs to help pregnant women quit smoking have been developed and evaluated,[5–8] formal antismoking programs are not a part of most prenatal care. The reasons why smoking cessation programs have apparently not been implemented are not known with certainty, but the cost of such programs is probably a major issue.

A recent analysis[9] of the cost-effectiveness of smoking cessation programs in pregnancy, however, showed that over $3 was saved for every dollar spent on smoking cessation. Their cost-effectiveness was also demonstrated in a study that examined such a program in a health maintenance organization (HMO) population.[10]

These two studies looked at cost-effectiveness by assuming a fixed program cost and comparing this cost with that of the adverse medical outcomes. An alternative approach to cost-effectiveness analysis is to examine the cost of adverse medical outcomes with an intervention and compare it with the cost without such an intervention. The difference in these two costs is the amount that the program could invest in the intervention and still "break even" economically.

Our analysis takes such a perspective. We calculated the aggregate costs of medical outcomes for a hypothetical prenatal program that included a formal smoking cessation intervention and compared them with a hypothetical prenatal program that did not have such an intervention. Assuming that any program must decide how to allocate fixed resources for a group of pregnant women, who comprise both smokers and nonsmokers, we therefore arrived at an estimation of cost per pregnant woman rather than of cost per pregnant smoker in our final result. Then, after arriving at this break-even point, we examined the extent to which this amount might vary from program to program, depending on the prevalence of smoking, the success of the cessation program, the incidence of adverse pregnancy outcomes in the population in question, and the cost of medical care.

Methods

Decision Analysis Models

We constructed two decision trees—one for infant outcome (Figure 1) and one maternal outcome (Figure 2)—to compare two strategies: (1) providing a

formal smoking cessation program for pregnant women who smoke, or (2) not providing a formal smoking cessation program. Probabilities used in the decision model were estimated based on published data (Table 1).

Data and Assumptions

Prevalence of Smoking at First Prenatal Visit (Node 1). Population-based data on smoking prevalence were obtained from the 1985 National Health Interview Survey (published in 1988).[11] Among survey respondents, 31.8% of the women between the ages of 18 and 44 who had given birth to a child within the past 5 years smoked cigarettes during the 12 months preceding pregnancy. Because 21.2% of the women quit smoking upon learning they were pregnant, we estimated a baseline probability of 25% for women still smoking at the time of their first prenatal visit (.318–(.318) (.212) = .25). This prevalence of .25 is the figure used for all the baseline analyses. The greatest variability in smoking prevalence was for women with different education levels. Therefore, probability estimates for the sensitivity analysis were based on a comparison of women with fewer than 12 years of education (probability .39) and women with 16 or more years of education (probability .08). These estimates take into account the before-pregnancy smoking rates and the chances of women quitting upon learning of pregnancy.

Quit Rate after First Prenatal Visit in Pregnant Smokers Who Are Provided with a Formal Program (Node 2). Randomized clinical trials of smoking cessation programs allow us to estimate quit rates attributable to formal smoking cessation programs. An optimal intervention program for pregnant women was implemented and evaluated by Sexton and Hebel,[7] who achieved the highest quit rate among pregnant smokers published to date (43%). Subtracting the quit rate in the control group (20%) in that study from the quit rate in the intervention group, we estimated a quit rate attributable to the program of 23%; this figure was used for the baseline analysis. In a study of a different smoking cessation program by Windsor et al.,[6] the quit rate attributable to the program was 12% (14% intervention, 2% control), which provided the lower probability estimate for our sensitivity analysis. We obtained the upper probability estimate of 29% by taking the difference in the smoking cessation rates between the intervention (43%) and control (14%) groups for men who participated in the Multiple Risk Factor Intervention Trial (MRFIT)[12] study. Although the MRFIT study evaluated men rather than pregnant women, we used it as the high estimate of the effectiveness of a smoking cessation program because MRFIT's smoking intervention

[a]women who smoke at the first prenatal visit.

was highly effective and may represent the maximum achievable for a formal cessation program. There is no assurance, however, that the same results could be achieved in pregnancy.

Spontaneous Quit Rate after First Prenatal Visit in Pregnant Smokers (Node 3). Spontaneous quit rates were assumed to be the same as quit rates in women in the control groups of randomized clinical trials. The baseline probability (.02) was derived from the 2% quit rate found among control group women participating in the study by Windsor et al.[6] The upper probability range (.06) was derived from a study by MacArthur et al.,[13] and the probability range of zero was chosen as an alternative, assuming that all women who are going to quit smoking do so prior to their first prenatal visit.*

*Regarding the estimates for nodes 2 and 3, we used data from randomized trials of smoking cessation programs to determine the net effect attributable to the smoking cessation program, which was estimated as the difference between the quit rates in the intervention group and the control group. This was the estimate used for the program arm of the decision tree. In the nonprogram arm of the decision tree, we also used this data on quit rates from the control groups to estimate the community spontaneous quit rate because these studies are among the few reliable sources of data on quit rates among pregnant women.

Infant Outcomes

Probability of LBW (< 2500 g) at Term (≥ 37 weeks) for Nonsmokers and Quitters (Nodes 4 and 6). Only incidence rates and relative risks were available in the literature. Thus, we used the following formula to calculate the probability of LBW at term for nonsmokers and quitters:

$$P_{NS} = \frac{I_{LBW}}{(RR_s)(Pv_s) + (Pv_{NS})},$$

where

P_{NS} = the probability of the outcome among nonsmokers and quitters,

I_{LBW} = the incidence of LBW at term for the population,

RR_S = the relative risk of LBW at term for continuing smokers,

Pv_S = the prevalence of smoking for the population, and

$Pv_{NS} = 1-Pv_S$.

The incidence rate of LBW at term (2.8%) was derived from US population-based data,[14] and the relative risk of term LBW for smokers (3.5) was obtained from a study by Ounsted et al.[15] The value used for the prevalence of smoking at the first prenatal visit was .25, and was derived as explained earlier.

Probability of LBW (< 2500 g) and Preterm (< 37 weeks) for Nonsmokers and Quitters (Nodes 4 and 6). The same formula was used to calculate the probability of LBW and preterm for nonsmokers and quitters, substituting a baseline overall incidence of preterm LBW of 3.8% and a baseline relative risk of preterm LBW of 1.4.[3,14]

Probability of LBW (< 2500 g) at Term (≥ 37 weeks) and Preterm (< 37 weeks) for Continuing Smokers (Node 5). The probability of each outcome among continuing smokers was derived from the probability of the outcome among nonsmokers and quitters and the relative risk of the outcome for continuing smokers:

$$P_S = (P_{NS})(RR_S),$$

where

P_S = the probability of the outcome among continuing smokers,

P_{NS} = the probability of the outcome among nonsmokers and quitters, and

RR_S = the relative risk of LBW for continuing smokers.

The range of relative risk estimates for continuing smokers was obtained from the Alameda County Low Birth Weight Study.[4] These were 4.5 to 5.1 for term LBW and 2.2 to 3.3 for preterm LBW.

Probability of Normal Birth Weight (> 2500 g) at Term (≥ 37 weeks) for Continuing Smokers (Nodes 4,5,6). The probability of normal birth weight at term for each smoking category was derived by subtraction:

$$P_{Norm} = 1-P_{Preterm}-P_{Term},$$

where

P_{Norm} = the probability of normal birth weight at term,

$P_{Preterm}$ = the probability of LBW and preterm, and

P_{Term} = the probability of LBW at term.

Sensitivity Analysis for Infant Outcome. Table 1 presents the range of probability estimates used in the sensitivity analysis. The first sensitivity analysis varied the prevalence of smoking at the first prenatal visit, using the lower (.08) and upper (.39) probability range values to determine the individual effect of smoking prevalence on the break-even point. Additional analyses were then conducted using the probability range estimates for each additional variable, varying only one estimate at a time. The analysis for the variable preterm LBW had values ranging from a low incidence of 3.2% to a high incidence of 7.3%, and the values for LBW at term were 2.4% and 5.0%, respectively.[14]

Because exact probabilities of infant outcomes could not be obtained from the literature and because the model appeared to be particularly sensitive to the relative risk of preterm LBW, a second sensitivity analysis examined the independent effects of varying the incidence rate for each outcome and relative risk estimate for preterm LBW. A final sensitivity analysis examined the independent effects of varying the incidence rate for each outcome and relative risk estimate for term LBW.

Maternal Outcomes

Probability of Antepartum Hemorrhage, Abruptio Placenta, and Placenta Previa for Smokers, Nonsmokers, and Quitters (Nodes 7, 8, 9). Studies[16–23] report elevated relative risks among smokers for placental abnormalities or bleeding during pregnancy. We converted these relative risks to probabilities using the formula cited earlier. An incidence of .01 for hemorrhage[24–26] and a relative risk of 1.43 for hemorrhage in smokers[23] were used in the baseline formula, and we obtained the probability of hemorrhage in continuing smokers (node 8) by the same method we used for infant outcomes.

Probability of Preeclampsia in Smokers, Nonsmokers, and Quitters (Nodes 7, 8, 9). The formula cited earlier was used to calculate the probability of preeclampsia in nonsmokers and quitters. The incidence rate of preeclampsia for pregnant women in the United States (.05) was obtained from studies cited in general obstetrics texts.[24,25] The baseline relative risk of preeclampsia for smokers (.42) was obtained from a recent case-control study,[27] which obtained a relative risk value similar to that obtained in older studies.[19] The reason for the lower relative risk of preeclampsia in smokers is uncertain, but it has been theorized that nicotine might inhibit the potent vasoconstrictor thromboxane, a substance found to be increased in studies in preeclamptic women.[28,29]

For the probability of preeclampsia in continuing smokers (node 8), we multiplied the relative risk in smokers (.42) by the probability of preeclampsia in nonsmokers and quitters (P_{NS}).

Probability of Births Not Complicated by Placenta Previa, Placenta Abruptio, Hemorrhage, or Preeclampsia (Nodes 7, 8, 9). The probability of a pregnancy not complicated by any of the above diagnoses was derived by subtraction.

Sensitivity Analysis for Maternal Outcomes. For the range of probabilities cited in Table 1, we varied the incidence rates of hemorrhage and preeclampsia through the ranges cited in the literature (.008 to .023 for hemorrhage and .05 to .10 for preeclampsia) while maintaining the relative risks for continuing smokers.

Additional sensitivity analyses varied, one at a time, the prevalence of smoking at the first prenatal visit, the probability of quitting smoking with a smoking program in place, and the probability of quitting smoking without a program in place.

Costs

Because true cost data cannot be obtained and results of this analysis are of most interest to third-party payors, charges were used as a proxy for costs. We included in our analysis only the direct medical charges for maternal care at delivery and for hospital care for newborns. With no national data available at the level of detail needed for this analysis, we approximated charges based on 1989 hospital and physician charges from two San Francisco Bay Area hospitals with perinatal databases. Because exact obstetric and newborn charge data are unavailable to compare San Francisco hospital charges with national averages, we varied the ranges of charges in our sensitivity analysis from 50% to 200% of the San Francisco charges, a range that includes most hospital charges in the United States.[30] The cost assumptions used in the model are summarized in Table 2 and were derived as described below.

Maternal Charges. We identified all patients discharged from the two study hospitals with antepartum hemorrhage or preeclampsia (ICD-9 codes 641.11, 641.21, 642.41, and 642.51)[31] between July 1 to December 30, 1989. We took a systematic random sample of women who delivered during the same period without hemorrhage or preeclampsia.

We did not include maternal hospitalization prior to delivery for any of the diagnoses, given that reliable data were not available on this parameter. However, predelivery charges are unlikely to make a major contribution to total charges. We obtained hospitalization bills for 94% of the women identified (124 of 132), and to each bill we added a standard obstetrician charge for the delivery of an infant.

For our mean baseline value for both infant and maternal charges, we eliminated the highest and lowest values, presuming them to be outliers.

Infant Charges. All infants diagnosed as term LBW born in the study period were identified using the obstetrical database of each hospital (n = 31). For infants who were preterm LBW and term not LBW, we took a systematic random sample of discharges from the same period (n = 30 for each diagnosis). For all these infants, we obtained hospitalization bills for 96% (87 of 91).

We approximated physician charges for preterm and term LBW infants by taking 20% of hospital charges for each infant, a number found in an earlier study,[32] to be the average physician charge for one of the same Bay Area hospitals used in our study. For the infants who were not LBW, we used a standard charge billed by the pediatric group of each institution for care of a normal newborn.

Sensitivity Analysis for Costs. Because hospital and physician charges for the same diagnosis may vary widely due to regional and institutional characteristics, we performed a sensitivity analysis by varying the amount charged for each diagnosis from 50% to 200%.

Results

Table 3 summarizes the estimated break-even cost per pregnant woman of a program for smoking cessation in pregnancy, based on various outcomes and population characteristics. Using our baseline assumptions and considering only infant outcomes, we estimate that $35 per pregnant woman is the largest amount the program could cost without exceeding the cost of care for LBW infants later on.

TABLE 2—Hospital and Physician Mean Charges for Selected Diagnoses Associated with Smoking in Pregnancy: San Francisco, 1989

	Number of Patients	Mean Charges ($)
Maternal		
Hemorrhage	35	11 056
Preeclampsia	51	8891
No hemorrhage or preeclamp	38	6794
Infant		
<37 wks, <2500 g	28	43 755
≥37 wks, <2500 g	29	4978
≥37 wks, ≥2500 g	30	2738

[d]Using the lower probability estimate of term LBW for nonsmokers and quitters (.015).
[e]Using the upper probability estimate of term LBW for nonsmokers and quitters (.031).

This amount is the estimated break-even cost. Using our baseline assumptions and considering both maternal and infant outcomes, the break-even cost of a program for smoking cessation during pregnancy is estimated to be $32 per pregnant woman. This is $3 less than the cost considering only infant outcomes because the higher risk of preeclampsia in nonsmokers results in an increase in expenditures.

Considering only infant outcomes, estimates of the break-even cost of such a program range from $28 to $67, depending on the assumed background incidence of preterm LBW in a population, and from $30 to $64, depending on the assumed incidence of term LBW (Table 3). When both maternal and infant outcomes are considered, the estimates of break-even cost are not much different.

Using the baseline assumptions, estimates of the break-even cost vary, depending on the percentage of women who smoke at the first prenatal visit. These estimates range from $12 per woman in a population with 10% smokers to $45 per woman in a population with 35% smokers (Figure 3).

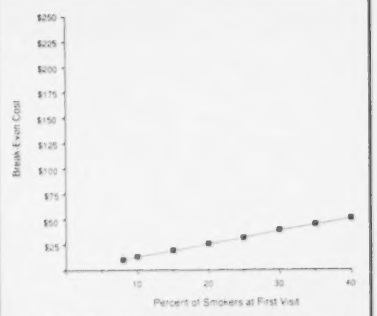

FIGURE 3—Estimated break-even cost of a program for smoking cessation during pregnancy, by prevalence of smoking at the first prenatal visit, considering both infant and maternal outcomes and using baseline assumptions for all other variables.

The estimated break-even cost strongly depends on assumptions about

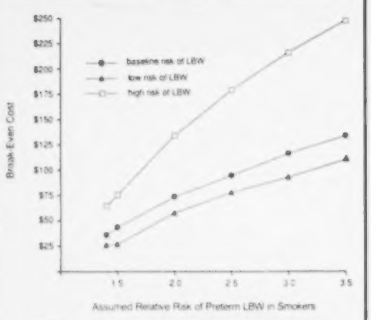

FIGURE 4—Estimated break-even cost of a program for smoking cessation during pregnancy for different assumptions about the relative risk of preterm LBW and several estimates of the background incidence of preterm LBW, considering both infant and maternal outcomes and using baseline assumptions for all other variables.

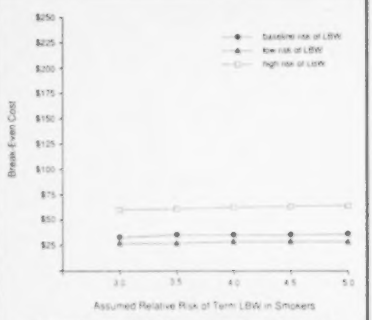

FIGURE 5—Estimated break-even cost of a program for smoking cessation during pregnancy for different assumptions about the relative risk of term LBW and several estimates of the background incidence of preterm LBW, considering both infant and maternal outcomes and using baseline assumptions for all other variables.

the relative risk of preterm LBW in continuing smokers (Figure 4). If the relative risk of preterm LBW in smokers is 3.0, as has been reported in one study of an urban Black population with a high background incidence of preterm LBW,[4] the break-even cost is $215 per woman. The estimated break-even cost does not depend on assumptions about the relative risk of term LBW in smokers (Figure 5).

TABLE 4—Estimated Break-Even Cost for Several Assumptions about the Cost of Various Outcomes, under Baseline Assumptions, Considering Both Maternal and Infant Outcomes

	Infant	Maternal	Net Cost ($)
Baseline	35	(−3)	32
Preterm LBW 50%	19	(−3)	16
Preterm LBW 200%	67	(−3)	64
Term LBW 50%	30	(−3)	27
Term LBW 200%	46	(−3)	43
Preeclampsia 50%	35	(+5)	40
Preeclampsia 200%	35	(−19)	16
Hemorrhage 50%	35	(−4)	31
Hemorrhage 200%	35	(−1)	34

As might be anticipated, assumptions about the effectiveness of the smoking cessation program influence estimates of the break-even cost. If the rate of smoking cessation were as low as 10% as a result of the program, the break-even cost drops to $12 per woman; however, if the program results in a net rate of smoking cessation as high as 29%, the break-even cost is $41.

Assumptions about the cost of care for a preterm LBW infant affect the estimate of the break-even cost more than assumptions about the cost of medical care for term LBW infants or for either of the maternal complications whose risk is increased in smokers (Table 4). No reasonable estimate of the cost of medical care for preeclampsia results in a net increase in expenditures when both infant and maternal outcomes are considered.

Discussion

Our analysis shows that, even when considering only direct medical charges related to hospitalization at delivery, a smoking cessation program that invests $32 for every pregnant woman seen in the facility would still break even economically in the short term. The number of dollars that could be invested in a smoking cessation program and still allow the program to break even is greater for populations with higher incidences of LBW, greater relative risks of LBW in smokers, and higher prevalence of smoking than the national average. However, at every level of LBW and of smoking prevalence found in the literature, money could be invested in a smoking cessation program and the program would still break even.

It should be noted that, consistent with the program perspective of our analysis described earlier, our "per patient" cost estimates apply to a cost for all patients, combining smokers and nonsmokers. To obtain the amount that could be invested per smoker, the "per patient" cost is divided by the prevalence of smoking in the population (e.g., in a baseline population with a smoking prevalence of 25%, $32/.25, or $128.00, could be spent for each smoker).

The largest cost associated with medical care of pregnant smokers and their infants is for infant care and not for care of maternal complications. There are three reasons for this. First, adverse infant outcomes are more common in smokers than are adverse maternal outcomes. Second, charges for adverse infant outcomes are much higher than those for maternal complications. Third, preeclampsia is less common in smokers than in nonsmokers.

The estimate of a break-even cost was most sensitive to assumptions about the incidence of preterm LBW and the relative risk for preterm LBW for smokers. For instance, in a population studied recently with a high incidence of and high relative risk for preterm LBW, the break-even cost was $237.[4] Although the prevalence of smoking at the first prenatal visit and the success rate of the formal smoking cessation program also affected the cost analysis, within the range of probabilities in the literature they did not produce as much variability in the break-even cost.

The break-even cost is moderately influenced by the quit rate for smokers attributable to the program, a rate that has varied considerably for programs studied.[6-8,12] Our baseline analysis is derived from a fairly optimistic quit rate of 23% obtained from an intensive intervention program for pregnant women that included one home visit, one telephone call per month, and twice-per-month mailings of smoking cessation literature.[7] More modest quit rates of 12% to 13.6% were

obtained by programs that included only short health education sessions and printed materials.[6,8] These more modest programs cost only $7.13 to $11 per pregnant smoker,[8,33] an amount below our calculated break-even cost when we substituted these quit rates into our analysis.

There are several important limitations to our study. First, we included only medical charges for the hospital admission for delivery and in-hospital charges for the neonate after delivery; therefore, our estimates are conservative. Second, we used local charge data because they are precise for LBW diagnoses. However, in our sensitivity analysis, we varied charges for each diagnosis from 50% to 200% of the mean charge, figures that include the charges for services at most US hospitals.[30] Last, we included only direct medical costs in our analysis. Cost analyses of other conditions often include indirect costs to society associated with years of potential life lost per premature death[34,35] and days of work lost due to illness.[34,36] Moreover, some studies have shown increased infant mortality in babies of smokers.[37,38] Still others suggest that children of smokers may have deficiencies in growth, intellectual development, and behavior[39–41] or an increased risk of otitis media.[42,43] Again, not considering these other adverse effects of smoking in pregnancy makes our analysis conservative.

A recent cost-effectiveness analysis was done by Marks et al.,[9] who hypothesized that $30 per pregnant smoker could be spent for a model smoking cessation program; with a 15% cessation rate, this would cost $23 505 300 nationally per year, or $4000 per LBW baby averted. The study compared this figure with NICU costs for LBW babies of smokers and surmised that the program would save $3.31 for every $1 invested. This ratio would increase to over $6 saved for every $1 spent if the costs of long-term care for infants with disabilities secondary to LBW were included. Although this study differed from the present analysis in several ways, the major difference was one of perspective: their analysis calculated the costs for a smoking cessation program nationally and compared them with the costs of care for LBW infants; our study takes a program perspective.

Importantly, our analysis includes a way of determining which variables the analysis is most sensitive to, and it provides a way for planners to input their own values for these population variables. Both our study and the Marks et al. study, as well as the HMO study mentioned earlier,[10] conclude that smoking cessation programs in pregnancy are cost-effective, whether from a national or a program perspective. Our analysis adds a dimension that allows program planners to determine how much to spend on these programs.

Program planners and administrators can use our analytic framework along with their own data to help decide how much to invest in a smoking cessation program. However, planners may want to consider factors other than the immediate break-even cost in their decision to include a smoking cessation program in their prenatal care. Considering the other long-range adverse medical, psychological, and societal outcomes of smoking, planners and society should be willing to invest in smoking cessation programs for pregnant women, regardless of their direct benefit of saving money. □

Finding Fault before Drilling: A Solution for Avoiding Radon

Dr. Irina Cech calls it a $2 solution. It's a solution, however, that could add up to a great deal of financial and health savings, not to mention saving headaches, particularly for those concerned with developing public water supplies.

Cech, professor of environmental health sciences and hydrology at the School of Public Health of The University of Texas Health Science Center at Houston, has some simple advice: to avoid a radon-contaminated well, don't drill within 4 miles from a salt dome, fault, or areas known or suspected to have uranium deposits.

Radon is a radioactive byproduct of uranium decay. Because it is odorless and colorless, there is nothing to alert well drillers or household residents unless testing occurs, Cech said.

"It is very costly to drill a well only to find out that the radon concentration is too high. By examining the area for fault lines before drilling, the problem can be avoided," she said.

Cech said uranium deposits appear primarily along the coastline of Texas, but dot other areas of the state as well. Radon deposits also collect along the flanks of salt domes, also common to the coastal areas. She said faults in the domes allow radon to "leak" upward. If an aquifer, or underground layer of earth saturated with water, happens to lie above or near a salt dome, radon may enter the water supply through the faults.

To date, Cech and her students have gathered almost 1000 water samples in Texas from public and individually owned domestic water wells and surface sources, along with wells used for livestock watering, industrial purposes, and oil production. Although radon can escape through the soil and seep through foundation cracks, in Texas it is primarily found in the water supply, Cech explained.

"Concentrations of radon were particularly high in public water wells along the Gulf Coast and in parts of west-central Texas," she said, explaining that the same area has one of the highest rates for respiratory cancer mortality in the nation.

"What we found was very interesting. When wells are developed around faults, a greater likelihood exists for encountering radon," she said.

The maximum acceptable limit of radon concentration in public drinking water that the Environmental Protection Agency has proposed is 300 pCi/L. According to the EPA, the lifetime risk of developing lung cancer from household water that contains 10 000 pCi/L of radon is roughly 3 to 13 in 1000.

"About 50% of the public water supplies measured by our group exceed the recommended standards. The highest concentration, 22 000 pCi/L, was found in southwest Texas near Refugio. In Houston, the highest observed was 6000 pCi/L," she said.

"This is of concern but should not be cause for alarm since radon levels are correctable," she said, explaining that public utilities will have until 1996 to meet the EPA requirements. Aerating the water supply would allow radon to escape before the water is piped to homes and businesses.

Radon in water is a problem only when the chemical is released from the water and enters household air. As one breathes, the radon breaks down further, causing small bursts of energy that can damage lung tissue. The chemical is released, for example, when people wash dishes and clothes, take showers, and flush toilets.

"Radon is more likely to be present in homes that are heavily insulated and airtight, which is extremely common in Texas. Drinking the water is not considered as much of a hazard as breathing the radon," she said. Economical ways to reduce risk from radon are to increase air flow in and out of the house and to refrain from smoking (scientific evidence indicates that smoking may increase the risk of exposure to radon).

Because radon appears primarily along the coastal borders, it is believed that similar situations exist in other parts of the world.

Low Birth Weight in Relation to Multiple Induced Abortions

ABSTRACT

Background. Most studies report that a single induced abortion does not increase risk for delivering a low birth weight infant in a subsequent pregnancy. However, the effect of multiple abortions has not been adequately evaluated.

Methods. This relationship was studied in 6541 White women who delivered their first child between 1984 and 1987. We compared the frequencies of low birth weight (less than 2500 g) among infants born to 1999 women without prior induced abortion and 1999 women with one abortion with the frequencies of low birth weight among infants born to women with two (n = 1850), three (n = 520), and four or more (n = 173) prior induced abortions.

Results. After adjustment for confounding variables, we found no linear relationship in risk of low birth weight among women with one (relative risk [RR] = 1.2, 95% confidence interval [CI] = 0.9–1.5), two (RR = 1.5, 95% CI = 1.1–2.0), three (RR = 1.3, 95% CI = 0.8–1.9), or four or more (RR = 1.6, 95% CI = 0.9–2.9) prior induced abortions.

Conclusions. These findings confirm earlier reports of little or no evidence of harmful effects on birth weight by one or by two or more induced abortions. We further report that risk is not significantly elevated even in women with three, four, or more prior terminations of pregnancy when compared with women with one or two abortions. (*Am J Public Health.* 1992;82:391–394)

Margaret T. Mandelson, MPH, Christopher B. Maden, PhD, and Janet R. Daling, PhD

Introduction

Since 1986, approximately 1.6 million induced abortions have been performed in the United States each year.[1] As the vast majority of women who undergo abortion eventually wish to deliver, it is important to identify possible deleterious effects of induced abortion on future pregnancy outcome. Many studies report that a single induced abortion does not increase a woman's risk for delivering a low-birth-weight infant in a subsequent pregnancy.[2–6] However, the effect of multiple induced abortions is less clear.[7] Multiple induced abortions may increase the likelihood of pregnancy loss or of preterm delivery resulting in a low-birth-weight infant in two general ways: cervical trauma from forced mechanical or rapid dilatation during the abortion procedure, or cervical and uterine adhesions due to curettage or infection.

Most studies of the risks of induced abortion on future reproductive outcome were conducted before a large proportion of women had the opportunity to have two, three, or more induced abortions. We report results from a population-based study of risk of low birth weight in women with multiple induced abortions prior to their first birth.

Methods

The Washington State birth certificate uses a check-box format to record information on demographic characteristics, complications of labor and delivery, and birth outcome. Information on history of prior induced abortions—specifically, the number of prior induced abortions and the date of the last induced or spontaneous abortion—was added to the birth certificate in 1984.

Women without a prior live birth who resided in one of the three most urban counties of Washington State (King, Pierce, and Spokane) and who delivered a live-born singleton infant between January 1, 1984, and December 31, 1987, were eligible for study. Because only a small proportion of Washington residents are non-White, this analysis was restricted to White women. Two thousand women without a history of induced abortion and 2000 women with one prior abortion were randomly sampled from the population using the birth certificate tapes. All eligible women with two (n = 1852), three (n = 522), and four or more (n = 173) induced abortions prior to their birth were identified. Six women were excluded for delivering infants with birth weights considered out of range (less than 450 g [n = 4], greater than 7000 g [n = 2]). The total study population consisted of 6541 White women.

Unconditional logistic regression[8] was used to provide parameter estimates of the risk of low birth weight (less than 2500 g) associated with one, two, three, and four or more prior induced abortions

At the time of the study, all authors were with the Division of Public Health Sciences at the Fred Hutchinson Cancer Research Center and with the Department of Epidemiology at the University of Washington in Seattle. Margaret Mandelson is with the Group Health Cooperative of Puget Sound and the Department of Epidemiology at the University of Washington; Christopher Maden is with the Seattle-King County Department of Public Health.

relative to no abortion history. Variables entered into the model as confounders included maternal age (19 years and younger, 20–24, 25–29, 30 years and older), marital status (married, not married), smoking during pregnancy (yes, no, unknown), median family income based on census tract of residence (under $15 000, $15 000–29 999, $30 000–44 999, $45 000 or more, unknown), and trimester when prenatal care began (first, second, third, or no prenatal care). Tests for linear trend in the logistic model were obtained by categorizing the exposure and entering the scored variable as continuous.[8] To separate the effect of multiple induced abortions on the risk of low birth weight from the risk of ever having had an abortion, the test of trend used one abortion as the baseline category.

Results

Women with multiple induced abortions tended to be older than women with one or no prior abortion (Table 1). Marital status was also associated with frequency of prior termination of pregnancy: a higher proportion of women with four or more induced abortions was unmarried (33.5%) compared with women with one abortion (24.0%) or no history of abortion (20.5%). Women with four or more induced abortions were more likely to smoke during pregnancy (41.6%) compared with women with one abortion (28.1%) or no prior abortions (18.0%).

Consistent trends between history of induced abortion and median census tract family income or trimester when prenatal care began were not observed (Table 1). Women with four or more prior abortions were less likely to receive prenatal care during the first trimester of pregnancy than women with no prior induced abortions (73.4% and 80.1%, respectively); however, the frequency of prenatal care beginning in the third trimester or the circumstance of no prenatal care at all did not vary appreciably according to abortion history.

Risk factors for low birth weight were strongly associated with history of multiple induced abortions. For example, 3.8% of women 30 years of age and older had four or more induced abortions prior to their first birth, compared with 3.0% among women 25–29 years of age, 2.1% among women 20–24 years of age, and 0.4% among women 19 years of age and younger (Table 1). Similarly, women who smoked during pregnancy were more than twice as likely to have had multiple abortions (four or more) compared with nonsmoking women (4.2% and 2.0%, respectively).

The crude proportion of infants with a birth weight of less than 2500 g varied between 4.4% among those born to women without a prior induced abortion and 9.6% among those born to women with four or more prior abortions (Table 2). After adjustment for maternal age, marital status, smoking during pregnancy, socioeconomic status as measured by median census tract family income, and trimester when prenatal care began, there was an indication that women with a history of one or multiple induced abortions prior to first delivery were at somewhat elevated risk (20% to 60%) for having a low-birth-weight infant compared with women with no such history. Smoking during pregnancy was an important con-

founder in these data, and adjustment for this variable reduced estimates of relative risk (RR) by approximately 15%. Most of the estimates were consistent with chance, and none was significantly different from another. Additional adjustment for method of delivery of the current pregnancy and for number of prenatal visits did not alter these findings. A trend of increasing risk of low birth weight with an increased number of prior abortions was not detected ($\chi^2_1 = 2.32, p = .13$).

TABLE 2—Standardized Relative Risks of Low Birth Weight (<2500 g) According to Abortion History

Number of Induced Abortions	N[a,b]	% Low Birth Weight	RR	95% CI
None	1941	4.4	1.0[c]	—
One	1944	5.7	1.2	0.9–1.5
Two	1788	7.7	1.5	1.1–2.0
Three	506	7.1	1.3	0.8–1.9
Four or more	167	9.6	1.6	0.9–2.9

Trend test (relative to one abortion): $\chi^2_1 = 2.32$, $P = .13$.
Note.—RR = relative risk, CI = confidence interval.
[a]Excludes women with missing data in key variables: age, marital status, and trimester prenatal care began.
[b]Adjusted for age (≤19, 20–24, 25–29, 30+), smoking during pregnancy (yes, no, unknown), marital status (married, unmarried), family income (<$15 000, 15 000–29 999, $30 000–44 999, $45 000 or greater, unknown), and trimester when prenatal care began (first, second, third, or no prenatal care).

Discussion

Several methodological issues associated with our study may have affected our findings. This analysis used information routinely collected on the Washington State birth certificate and is limited by the accuracy of that data. The check-box format on the birth certificate has improved the accuracy of reporting pregnancy complications,[9] but the reliability of other information is less certain. It is possible that underreporting of induced abortion may have occurred. Misclassification of this exposure, particularly among women categorized as having no prior abortion history, would bias our results toward little or no association. Previous studies have questioned whether women will admit to having had an induced abortion.[10–12] However, these studies were conducted during the previous decade, when women might have been more reluctant to discuss induced abortion and when some of the abortions may have been illegally obtained. Furthermore, a recent study conducted in the same geographic area[13] found that self-reported history of induced abortion obtained through personal interview agreed closely with medical chart review.

Analyzing computerized birth certificate records may be one of the few ways to study this issue using a population-based design, but such records provide limited information on confounding factors. For example, information such as maternal education, alcohol use, and illicit drug use during pregnancy is not routinely collected. Additionally, variables on the certificate, such as average family income based on census tract of residence and dichotomized smoking information, may provide inadequate statistical control for the effect of socioeconomic status and smoking behavior. Residual confounding may be present, and our estimates of relative risk may be spuriously high.

There is evidence to suggest that the frequency of late complications may vary by the abortion procedure used.[14–15] Abortion method and gestational age at termination were not known for the women in our study. It is likely, however, that most of the abortions were performed early in pregnancy and by vacuum aspiration, given that more than 95% of induced abortions performed in the United States in recent years use this method and approximately 89% are conducted during the first trimester.[16]

Among the 94 939 White women who delivered their first live-born infant in Washington State between 1984 and 1987, 16.2% had terminated one or more prior pregnancies with an induced abortion. Although most of these women had only had one prior abortion, 3.4%, 1%, and 0.3% had, respectively, two, three, and four or more pregnancies terminated. The rate of low birth weight among infants born to women with one or more prior induced abortions was higher than it was among infants born to women with no prior induced abortions. However, after adjusting for the confounding effects of maternal age, marital status, smoking, family income, and prenatal care, we found very little, if any, increased risk associated with multiple induced abortions. Most of the estimates were consistent with chance and were of a magnitude that might be explained by residual confounding. We were unable to detect a significant linear trend in risk with an increasing number of prior induced abortions.

In light of the overall lack of association reported here between previous induced abortions and low birth weight, a consideration of study power is warranted. This study could have detected a 1.4-fold elevation in risk of low birth weight among women with one prior abortion compared with women with no prior abortions at $\alpha = .05$ and $1-\beta = .80$. Comparing women with two, three, and four or more prior abortions, the same power could have detected relative risks of 1.4, 1.7, and 2.2, respectively.

The association between induced abortion and poor reproductive outcome has been well studied and reviewed;[7] however, few studies have evaluated the specific effects of multiple induced abortions. Further, no previous study has had adequate numbers of women with two, three, or more induced abortions prior to a first birth with which to estimate the risk of low birthweight associated with each of these higher frequencies of induced abortion.

Our findings closely agreed with and extended reports by other investigators, whose data have been limited to the more general grouping of two or more prior abortions. Most recently, Bracken and coworkers[4] report no evidence for a causal relationship between one (RR = 0.86) or two or more (RR = 1.14) prior abortions and low birth weight in women delivering their second or third pregnancy. Linn et al.[5] report that women with one prior abortion have a risk of 0.74 to 1.17 for having a low-birth-weight infant relative to that of women who had not undergone an induced abortion, and that women with two or more prior abortions have a risk of 0.88 to 1.79. Our results also confirm earlier findings reported by Daling and Emanuel[6] who observed no elevation in risk of low birth weight associated with one or more induced abortions.

However, these results do not agree with a study by Seidman et al.,[17] which found an excess risk of low birth weight associated with one, two, and three or more prior abortions. Based on a series of

deliveries occurring in Israel between 1974 and 1976, women with one or more prior abortions were found to have 1.3 times the rate of low birth weight relative to women with no previous abortions. Among women delivering their first child, the unadjusted percentages of low birth weight for women with one, two, and three or more prior abortions are 1.4 to 2.2 times higher than the frequencies found in our data. These conflicting findings may be due to differences in abortion procedure and in method of cervical dilatation. Induced abortions conducted in Israel between 1974 and 1976 were generally performed by dilatation and curettage or, for late abortion, intrauterine saline injections. In contrast, the majority of abortions in our sample, as previously noted, were most likely performed by vacuum aspiration during the first trimester.

An association between multiple induced abortions and very low birth weight has been reported.[18] Australian perinatal records of births between 1982 and 1983 show that women with two or more induced abortions are 3.6 times more likely to deliver an infant weighing less than 1000 g relative to women with no abortion history. Information on confounding factors such as smoking and socioeconomic status was not recorded on these perinatal records, and analysis of risk is based on crude percentages of very low birth weight. Few women in our sample (n = 36) delivered infants of very low birth weight (less than 1500 g), and it was not possible to estimate risk of this outcome independently of the effects of important confounding factors.

These results apply only to White women delivering their first child and to the risk of only one adverse pregnancy outcome. They confirm earlier findings that show little or no evidence of harmful effects on birth weight by one or by two or more induced abortions, and we further report that this risk is not significantly elevated even in women with three, four, or more prior terminations of pregnancy when compared with women with one or two abortions. Over half of all abortions conducted in the United States during the study period were performed on women without a prior live birth.[16] The results of the present study together with those of other reports suggest that, if there is any increase in risk for having a low-birth-weight infant in the first delivery following multiple induced abortions, it is likely to be modest. □

Mortality, Disability, and Falls in Older Persons: The Role of Underlying Disease and Disability

ABSTRACT

Background. Falls are prevalent in older persons and can have serious consequences.

Methods. Data from the Longitudinal Study on Aging were analyzed to study the relationship between falls and both mortality and functional status in 4270 respondents age 70 and over. The effects of demographic traits, chronic conditions, and disability present at baseline were controlled for by means of multivariable analyses.

Results. Risk of death within 2 years was greater for both single fallers (crude odds ratio [OR], 1.5; 95% confidence interval [CI], 1.1–2.0) and multiple fallers (crude OR, 2.2; 95% CI, 1.7–2.8). This excess risk was dissipated when selected covariates were added to the model. No crude or adjusted association was evident between single falls and functional impairment; however, multiple falls were an independent risk factor (adjusted OR, 1.6; 95% CI, 1.2–2.0).

Conclusions. Multiple falls in older persons increase risk of functional impairment and may indicate underlying conditions that increase risk of death. (*Am J Public Health.* 1992;82:395–400)

Introduction

Falls are prevalent in older persons, and the incidence of falls increases with age. Twenty-eight percent to 33% of those aged 65 and older report having fallen over a 1-year period, and the rates approach 50% in those over 80.[1–3]

Falls can have serious consequences in older persons. People over the age of 65 have the highest mortality rate from injuries, and the largest single cause of injury mortality in this group is falls.[4] A study using the Major Trauma Outcome Study database found an 11.7% case fatality rate for falls in geriatric patients,[5] and recent data from the Dade County, Fla, community-based Study to Assess Falls Among the Elderly[6] found 2.2 deaths per 100 fall injury events that came to medical attention, not including deaths that occurred after discharge from the hospital. There is some indication that longer-term outcomes of falls may be even more serious than the short-term outcome statistics would indicate. A British study of 125 people aged 65 and older who fell in the home reported a 1-year mortality rate of 26%, compared with 6% in a control group, although none of the deaths in those who fell were reported as being from fall-related causes.[7] Nonfatal falls can also have severe consequences in the aged: the Dade County study[6] found that about half of the fall injury events occurring at home and requiring hospitalization resulted in discharge to a nursing home.

These findings raise several questions: Are falls in older persons related to increased mortality and disability? If so, to what extent are these adverse outcomes due directly to falls, rather than to factors associated with both falling and mortality or disability outcomes?

Several studies[1–3,8] show the relationship between falling and mobility disorders, diseases, sensory losses, medication use, and limitations in activities of daily living (ADLs). It has been argued that the elevated mortality associated with falling is caused by conditions that predispose toward falling, rather than from resulting trauma.[7] Also, it has been suggested that a person who may already have compromised gait and balance systems may fall when a new illness or condition, even one that seems minor or unrelated to falling per se, occurs.[9] Tinetti[10] showed that a fall risk score, derived from the number of chronic diseases present, predicted risk of falling in older persons better than did a mobility score alone. She concluded that falling "appears to result from the accumulated effect of multiple specific debilities."

Researchers have found that those who experience repeated falls differ in some respects from those who have single or occasional falls. Risk factors for single falls appear to be less robust than those for multiple falls.[8] One suggestion is that occasional falls result primarily from extrinsic factors, such as environmental haz-

Education	Heart disease	Eating
	Stroke	Transferring
	Vascular disease	Walking
	Diabetes	Going out
	Cancer	Toileting
	Visual deficit	
	Hearing deficit	
	Thinness	

ards, while repeated falls are the result of intrinsic factors, such as demographic factors, chronic disease, and disability.[9]

We have used data from the Longitudinal Study on Aging (LSOA) to examine the relationship between falls, chronic disease, disability, and mortality; the LSOA population is a larger and more diverse sample population than has been examined in previous studies of falling. Specifically, we determined the following:

1. Crude 2-year mortality rates in those who had and those who had not fallen in the year prior to the baseline (1984) LSOA survey
2. The extent to which history of falling in the past year predicts subsequent mortality, when demographic factors, chronic conditions, and functional disabilities present at baseline are controlled for
3. The extent to which history of falling predicts decreased functional ability after 2 years, when demographic variables, chronic conditions, and disabilities present at baseline are controlled for.

Methods

The LSOA Population

For this analysis we used data from the 1986 longitudinal follow-up of persons 70 years of age and older from the Supplement on Aging to the 1984 National Health Interview Survey (NHIS) conducted by the National Center for Health Statistics. The purpose and design of this survey is described elsewhere.[11,12]

Of the persons selected for reinterview in 1986, 4270 met our criteria: they had had a follow-up interview or their vital status was known, and complete information was available for them on variables germane to this study.

Those who had died prior to follow-up and those who were missing pertinent follow-up information were deleted from disability outcome analyses; thus the sample size for this outcome was 3706.

The 1984 baseline interview included self-reported data on demographic variables, health conditions (including history of falls in the past year), and functional status; the 1986 follow-up reported vital status and functional status but did not obtain additional information about health conditions or falls.

Outcome Variables

Mortality. Mortality at follow-up was defined as death validated through a match with the National Death Index (NDI), or report of death for those for whom no NDI match was found. Five hundred twenty-five of the 4270 individuals used in this analysis had died during the 2-year follow-up period; cause of death was not available at the time of this analysis.

Disability. Functional disability at both baseline and follow-up was determined by reported difficulty with a modified selection of ADLs: bathing, dressing, eating, transferring from bed or chair, walking, going out, and toileting. Individuals were coded as having difficulty with an activity if they responded "yes" when asked if they had difficulty accomplishing that activity. Missing responses were deleted, as were those from individuals who reported that they did not perform the activity for reasons unrelated to health or physical ability. "Don't do" responses constituted less than 0.5% of responses for each individual ADL.

The dichotomous disability outcome variable was defined as having difficulty with a greater number of ADLs in 1986 than in 1984. Individuals having difficulty with fewer ADLs at follow-up (884, or 20.7%), as well as those whose functional ability had not changed, were defined as not having decreased functional ability.

Further multivariate analysis of the association of falls and subsequent disability was carried out with a categorical disability outcome variable: the number of ADLs reported at follow-up.

Exposure Variables

Respondents to the 1984 interview were asked if they had fallen in the past 12 months. If they answered "yes" they were asked if they had fallen once, or more than once; 401 individuals reported one fall and 405 reported more than one. Single and multiple fallers were compared separately to the reference group (those who had not fallen). In the multivariable analyses this comparison was accomplished with two dummy variables.

Covariates

Covariates used in the multivariable logistic regression models are listed in Table 1.

Because 14% of the baseline responses and 33% of the follow-up responses were completed by proxy respondents, and proxy status was significantly associated with multiple falls at baseline, a variable was included in each multivariable model to indicate proxy status of the respondent.

Other covariates were included in the models if they had been shown to be associated with falls in the LSOA population or in previous studies or (2) if they had been shown to be associated with mortality or disability in the LSOA population or in previous studies, and (3) if, in addition, the variable had sufficient responses for meaningful analysis.

Covariates were categorized as demographic, chronic condition, or disability variables. To examine the effect of specific covariates, we added all variables in a given category to the model as a block. Additionally, because our primary interest was to examine the effect of controlling for multiple chronic conditions and disabilities rather than to examine the effects of specific covariates upon the outcomes, we created two ordinal variables to represent the numbers of reported chronic conditions (0–11) and disabilities (0–7).

Demographic covariates were age in 1984, sex, marital status, and education (two dummy variables were used to describe "low" and "high" education, compared with the reference category of 9–12 years). Those missing data for education were assigned mean values (9.56 years for males, 9.99 for females). Education was included both as a surrogate for socioeconomic status (because 20% of the respon-

dents had not answered the question about income) and because there appears to be an inverse relation between educational attainment and mortality in middle-aged and older Americans.[13]

Chronic condition variables included osteoporosis/hip fracture, arthritis, hypertension, heart disease (myocardial infarction, rheumatic heart disease, coronary heart disease, and "other heart attack"), stroke, diabetes, vascular disease, cancer, visual deficits, hearing deficits, and thinness (body mass index < 21 kg/m^2). Low body mass index was included because the body weight at which minimal mortality occurs increases with advancing age[14] and the curve of mortality risk versus declining body mass index rises steeply for body mass indexes of 21 and less in middle-aged and older females.[15]

Disability covariates consisted of reported difficulty with individual ADLs at baseline (1984), as described above.

Analytical Methods

Our analytic strategy was to determine risks for 2-year mortality and functional decline in those with and without a history of falling, and then to examine the same questions in multivariable models, controlling for demographic characteristics, preexisting health conditions, and disabilities that could be related to an individual's propensity to fall as well as to risk of death or future disability.

Statistical analyses were performed with the SAS package.[16] All univariate and multivariate analyses were weighted; the results are thus applicable to the US population age 70 and over.

Multiple logistic regressions were performed with the LOGIST procedure.[17] The RTILOGIT procedure[18] was used with mortality and dichotomous disability outcome models to generate variances incorporating the weighting system used to compensate for the complex sampling design of the survey. RTILOGIT could not be used in models with an ordinal outcome variable; however, because the weighted variances generated in the dichotomous outcome model were so close to those obtained with the LOGIST procedure (within .0001 in all cases), we used standard deviations generated from the LOGIST procedure to calculate confidence intervals for the ordinal outcome models. Before ordinal outcome regressions were run, the partial proportional odds model[19] was used to test for nonproportionality of increasing response (number of ADLs) with exposure (falls); because this was nonsignificant, proportionality, or a common odds ratio between any dichotomous division in the outcome variable scale, could be assumed.

All multivariable models included the block of demographic covariates and a variable indicating the proxy status of the respondent.

Results

Descriptive and Cross-sectional Statistics

Unweighted descriptive statistics for the LSOA subpopulation used in this analysis are shown in Table 2. The extent to which the covariates used in the multivariable analyses are associated with having fallen is shown in Table 3. Compared with those who had not fallen, those who had fallen once in the year prior to baseline interview were significantly more likely to be female, age 80 or over, thin (BMI < 21), and unmarried, and to report the presence of visual or hearing difficulties, osteoporosis/hip fracture, arthritis, vascular disease, and difficulty with each of the ADLs. Those who had fallen more than once had characteristics similar to those listed above, and in addition were more likely to have less than 9 years of formal education, to have had the baseline questionnaire completed by a proxy, and to report the presence of hypertension, heart disease, stroke, diabetes, and cancer.

Mortality Outcome

Of those who reported no falls in the year prior to their 1984 interview, 11.9% were deceased by 1986, compared with 18% of those reporting one fall and 25.4% of those reporting two or more falls. The corresponding crude odds ratios were 1.5 (95% confidence interval [CI], 1.1–2.0) for single falls and 2.2 (95% CI, 1.7–2.8) for multiple falls (Table 4).

In the multivariable analysis, the odds ratios for single and multiple falls decreased slightly in magnitude, to 1.4 and 2.0, respectively, but remained significant at $P < .05$ when demographic variables and proxy status were controlled for (Table 5). When the block of chronic conditions was added to the model, the mortality odds ratios decreased further. With disability at baseline added to the model with demographic and proxy variables, the odds ratio for death decreased even more, losing significance for single falls, and when chronic conditions and disabilities were added together, the mortality odds ratios for single and multiple falls converged at 1.3 (95% CIs, 0.9–1.7 and 0.9–1.8, respectively). Substituting number of chronic conditions or disabilities for the individual conditions had almost no effect on these results.

Significant covariates in the full model (containing demographics, proxy status, individual chronic conditions, and individual disabilities) were age, male sex, high education (protective), thinness, arthritis (protective), stroke, cancer, difficulty bathing, and difficulty toileting. In the model with number of chronic condi-

tions and disabilities, the same demographic covariates were significant, along with the number of chronic conditions and number of disabilities.

Disability Outcome

In the univariate analysis (Table 6), single falls were not significantly associated with subsequent increased disability, but those who had fallen more than once were more than twice as likely to report difficulty with additional ADLs as were those who had fallen once.

Single falls did not predict increased disability in any of the multivariate models, whereas multiple falls were significant predictors in all models, both dichotomous and ordinal (Tables 7 and 8). As with the mortality outcome models, the addition of successive groups of covariates caused a decrease in the magnitude of the disability odds ratios for multiple falls. Substitution of numbers of chronic conditions or ADL difficulties present at baseline for the groups of individual conditions had little effect on the odds ratios.

A similar trend was seen in the categorical outcome models, with the disability odds ratio for multiple falls decreasing in magnitude but remaining significantly greater than 1.0 as successive blocks of covariates were added (Table 8).

Significant covariates in the categorical full model with individual chronic conditions were age, being married (protective), osteoporosis/hip fracture, arthritis, hypertension, heart disease, stroke, diabetes, proxy status, and number of functional disabilities at baseline. In the model with number of chronic conditions rather than individual chronic conditions, there was a significant association between this variable and decreased functional ability.

Discussion

Although the univariate analysis demonstrated a significant association between falls and 2-year mortality in this nationally representative population, the results of the multivariable analyses support the hypothesis that elevated mortality associated with falling in older persons is largely due to the presence of multiple chronic diseases and disabilities in those who are prone to fall. Falling is not an independent predictor of mortality when chronic disease and functional disability are controlled for, but it tends to be associated with these conditions in our baseline data. Our findings are consistent with other studies implicating underlying disease and disability as possible causal factors in falling.

Single falls do not appear to be associated with increased functional disability over a 2-year follow-up, but multiple falls are, and they remain significant, if not independent, predictors even when chronic conditions and functional disabilities present at baseline are controlled for. This could be due to injuries not included in the model, to other chronic diseases associated with both falls and disability that we were not able to control for (e.g., parkinsonism, Alzheimer's disease), or to these and other chronic diseases that might be undiagnosed and thus unreported. It has also been noted that fear of falling can cause people to restrict their normal activities[8]; it is possible that a repeat faller might limit his or her activities to the point where ADLs are affected. Although a relatively small proportion of falls result in serious injury (such as fractures or severe soft tissue trauma), it is possible that less serious injuries (as well as outcomes such as anxiety about further falls and loss of confidence) may disproportionately affect older persons.

In light of Tinetti's findings implicating number of conditions as one of the most important risk factors for falls, it is

Two or more	2.0 (1.5–2.6)	1.6 (1.2–2.1)	1.4 (1.1–1.9)	1.3 (0.9–1.7)	1.6 (1.2–2.1)	1.4 (1.1–1.9)	1.3 (1.0–1.7)

Note. All models are weighted and control for proxy responses.

interesting that controlling for number of chronic diseases or functional disabilities present at baseline had an effect on the mortality and disability odds ratios for falls almost identical to the effect of controlling for the individual conditions. An examination of this LSOA subpopulation suggests a possible explanation with regard to chronic condition variables in the mortality outcome models. As shown in Table 1, the majority of individuals (nearly 80%) reported having from one to four of the chronic conditions we examined in our models. The most prevalent chronic conditions reported were arthritis (55.2%), hypertension (46.1%), hearing deficits (39.7%), and visual deficits (37.0%), none of which was a significant risk factor for mortality in the full model. An assumption that the majority of people reporting chronic conditions at baseline suffer from more than one of these prevalent but nonfatal conditions could explain the similar effect of controlling for number of conditions as opposed to individual conditions. In support of this assumption, a recent analysis of comorbidities in respondents aged 60 and older to the National Health Interview Survey and the Supplement on Aging found that arthritis and hypertension were the most common comorbid conditions, reported by 24.1% of that population, followed by arthritis and cataract (11.7%).[20]

These data provide an interesting note on the relationship between single and multiple falls. Although the crude mortality odds ratio was much higher for multiple than for single falls, the difference between the two decreased as covariates representing "intrinsic" characteristics were added to the model. When demographic, chronic condition, and disability variables were controlled for simultaneously, the odds ratios and test-based confidence intervals were nearly identical for single and multiple falls, and neither were significant predictors of mortality. On the other hand, multiple falls predicted increased disability and single falls did not, even when all covariates were added to the model. The most likely source of bias in comparisons of single and multiple falls—that a substantial number of single-fallers had additional falls prior to follow-up—would tend to obscure this difference. Perhaps there is a temporal difference; those experiencing multiple falls earlier in time may be more likely to become disabled sooner.

TABLE 6—Functional Ability Status and Crude Disability Odds Ratios

Falls in 1984	No Additional Disability in 1986[a]	Additional Disability in 1986	Odds Ratio (95% CI)
None	2090	819	—
One (n = 3306)	271	126	1.2 (0.9–1.5)
Two or more (n = 3309)	210	190	2.2 (1.8–2.7)

Note. CI = confidence interval.
[a]Includes those reporting difficulty with fewer activities of daily living (ADLs) in 1986 than in 1984.

There are also implications for caregivers and clinicians in the interrelationships of mortality, disability, chronic conditions, and falls. As individuals accumulate larger numbers of chronic conditions and disabilities—even those that are individually relatively benign—their potential for experiencing adverse outcomes from falls increases substantially. These individuals may be most in need of interventions to reduce both the risk and the severity of falls. Likewise, multiple falls in older persons should be taken seriously by physicians and other caregivers as indicators of possible underlying conditions that could increase risk for functional dependency or death within the next few years. □

Living Arrangements and Survival among Middle-Aged and Older Adults in the NHANES I Epidemiologic Follow-up Study

ABSTRACT

Background. There is concern about but little information on how living alone affects the health and survival of older adults.

Methods. We examined the association between living arrangements (living alone, with a spouse, or with someone other than a spouse) and survival among 7651 adults, aged 45 to 74 years in the National Health and Nutrition Examination Survey (NHANES I) (1971–1975) and traced at the NHANES I Follow-up Study (1982–1984), to see whether certain sociodemographic factors (race, education, income, and employment), health behaviors (alcohol, smoking, physical activity, and obesity), or chronic medical conditions were influential in the association.

Results. We found a stronger association of living arrangements with survival for men than for women, and for middle-aged men than for older men. For men, those living alone and those living with someone other than a spouse were equally disadvantaged in terms of survival. Income, race, employment, and physical activity influenced the association of living arrangements and survival, but their impact varied by age, gender, and living arrangement.

Conclusion. Living arrangements had a weak impact on survival among men, but had no effect among women. (*Am J Public Health.* 1992;82:401–406)

Introduction

In the United States, the number and proportion of elderly persons who live alone have increased dramatically since 1960.[1] As of 1989, approximately 30% of all persons aged 65 years and older lived alone, and almost four fifths of those solitary elders were women.[2] There has been a trend for older adults to live alone if they are no longer married, and this pattern is likely to continue.[3]

Numerous studies indicate that married persons have lower mortality rates than unmarried ones[4–13] and that differences in mortality by marital status are more pronounced for men than for women.[9–13] However, few studies have addressed whether there is additional mortality risk associated with being unmarried and living alone, or whether living arrangements affect survival more or less strongly for older adults compared with middle-aged adults.

There is concern that older adults who live alone may be particularly vulnerable to poverty, social isolation, loneliness, decreased psychological well-being, and adverse health outcomes.[14–17] And there is considerable evidence among older or middle-aged adults that mortality is associated with sociodemographic characteristics[18–24] (age, sex, race, education, income, and employment), health behaviors[19,22,25–27] (alcohol consumption, smoking, obesity, and physical activity), and health status.[19,28,29] However, there is little existing epidemiological information about the quality of life, health behaviors, and health status of the elderly who live alone, or about the impact of living alone on survival.[30]

Because many older adults want to live independently, they may be likely to live alone until their health declines to the point where they can no longer function independently; they then move in with others or are institutionalized.[31,32] Thus, those living with someone other than a spouse may be at higher risk of mortality because their poor health led them to live with someone.

Evidence from four national data sets suggests that age, sex, socioeconomic status, and other factors may influence the diet and health of the elderly living alone.[30,33–35] These findings highlight the need to examine whether specific sociodemographic, behavioral, or health characteristics that may differ by type of living arrangement affect the association of living arrangements with survival. In this report, we examine the association of living arrangements with subsequent survival over a 7- to 13-year period for a sample of US adults aged 45 to 74 years from the National Health and Nutrition Examination Survey 1971–1975 (NHANES I)[36,37] who were traced in the NHANES I Epidemiologic Follow-up Study 1982–1984 (NHEFS).[38] We focused on four research questions: (1) Do persons living alone have shorter survival times than those living with a spouse or with someone other than a spouse? (2) Are living arrangements more strongly associated with survival time for men

(4) Do specific sociodemographic characteristics, health behaviors, or chronic medical conditions known to be associated with mortality account for patterns in which living arrangements are associated with survival?

Methods

Study Sample

The NHANES I, a national probability sample of the civilian, noninstitutional population aged 1 to 74 years, collected demographic, medical history, clinical, and laboratory information.[36,37] The NHEFS 1982–1984 attempted to trace all 14 407 NHANES I persons aged 25 to 74 years to determine whether they were still alive and to conduct in-depth interviews, collect selected physical measurements, and obtain health facility records and death certificates.[38]

Analyses in this report are restricted to the 7957 persons aged 45 to 74 years at NHANES I, of whom 7651 (96%) were traced at follow-up. Among those traced, 5769 (75%) were alive and 1882 (25%) had died.[38] Death certificates were obtained for 96% of the deaths, and proxy reports of death were obtained for the remainder.[38]

Mean length of follow-up for the survivors was 10 years. Nonsurvivors died an average of 5.5 years after NHANES I. Madans and colleagues have reported that the survival experience of the 1982–1984 NHEFS cohort is representative of the survival experience of the total US population.[39] Table 1 describes the sample sizes and number of deaths by age, sex, and living arrangements for persons included in these analyses.

Variables

Baseline (NHANES I) living arrangements were categorized as living alone, living with a spouse, or living with someone other than a spouse. Baseline sociodemographic variables included age (45 to 54 years, 55 to 64 years, 65 to 74 years), sex, race (White or other), education, income (dollars per household member), and employment (employed or not, employed outside the home, during the previous 3 months). Those not employed included those who were keeping house, retired, laid off from work, looking for work, or ill or unable to work during the previous 3 months. Persons with missing income data (n = 319) were excluded from analyses involving income.

Health behavior variables included body mass index (weight [kg]/height [m^2]), physical activity, alcohol consumption, and smoking. The measures of physical activity were nonrecreational activity (inactive, moderately active, or very active) and recreational activity (little or none, moderate, much). Daily alcohol consumption was divided into four categories: none, one drink per day, two drinks per day, or more than two drinks per day, based on questions about the subject's usual 24-hour frequency of alcohol consumption. Smoking behavior was categorized as having never smoked, having formerly smoked, or currently smoking. Only a random subsample of the NHANES I sample was asked about smoking (n = 3968 for those in this report), whereas all respondents or proxies of decedents were asked about smoking at the follow-up. For those persons not asked about smoking at baseline (n = 3080 for these analyses), baseline smoking status was determined from a lifetime smoking history ascertained at NHEFS 1982–1984. A high level of agreement has been found between NHANES I baseline smoking responses and baseline smoking as determined in the NHEFS.[40] For persons who were missing smoking information at both NHANES I and NHEFS (n = 603 for these analyses), smoking status was imputed using the method developed by Kleinman and colleagues.[41]

History of chronic medical conditions was ascertained from questions about whether a doctor had ever told the respondents that they had any of 36 conditions. In addition, blood pressure readings were obtained, and persons were classified as hypertensive if they had either a systolic reading of 165 mm Hg or greater or a diastolic reading of 95 mm Hg or greater, or were taking medication for hypertension. For these analyses, 19 of the conditions that are frequent causes of death[42] were grouped into nine categories (pulmonary disease, heart disease, hypertension, stroke, gastrointestinal disease, diabetes, kidney disease, malignant tumor, and fracture). The number of reported disease categories was counted and categorized (none, one, or two or more categories).

Statistical Analyses

We examined the association of living arrangements from NHANES I with subsequent survival from NHEFS using Cox proportional hazards models,[43] which were calculated by the PHGLM procedure in SAS.[44] Separate proportional hazards models were fitted in each of six NHANES I age-sex groups. Using a standard graphical method,[43] we examined the adequacy of the proportional hazards assumption by plotting the log-minus-log survivor function by living arrangement group within each of the six age-sex groups. For each age-sex group, the plots exhibited nearly constant separation, suggesting that the assumption of proportional hazards was reasonable.

We initially computed estimates of the age-adjusted relative hazards corresponding to living arrangements, and then we examined the role of sociodemographic characteristics, health behaviors, and chronic conditions in the living arrangements–survival association by calculating the relative hazards estimates adjusted for these variables. All analyses were also adjusted for age (in individual years) within each age group. Interactions between living arrangements and each of the sociodemographic, behavioral, and chronic conditions variables were examined by including products of the indicator

variables for living arrangements and each variable as covariates in the proportional hazards models and testing the statistical significance of the interaction parameters using the likelihood ratio test. No interactions were found.

The NHANES I sampling design, which included differential sampling rates by age, sex, and income, was incorporated into our analyses. The sample proportions of persons in the three living arrangement groups were calculated using the NHANES I sample weights (Figure 1). Additionally, all proportional hazards models were fitted separately by sex- and design-compatible age groups while the final models were adjusted for income and race. Our proportional hazards analyses did not incorporate the NHANES I cluster sample design into the standard error estimates. Similar analyses of NHANES I survival data found design effects for Cox regression coefficients near 1.[20]

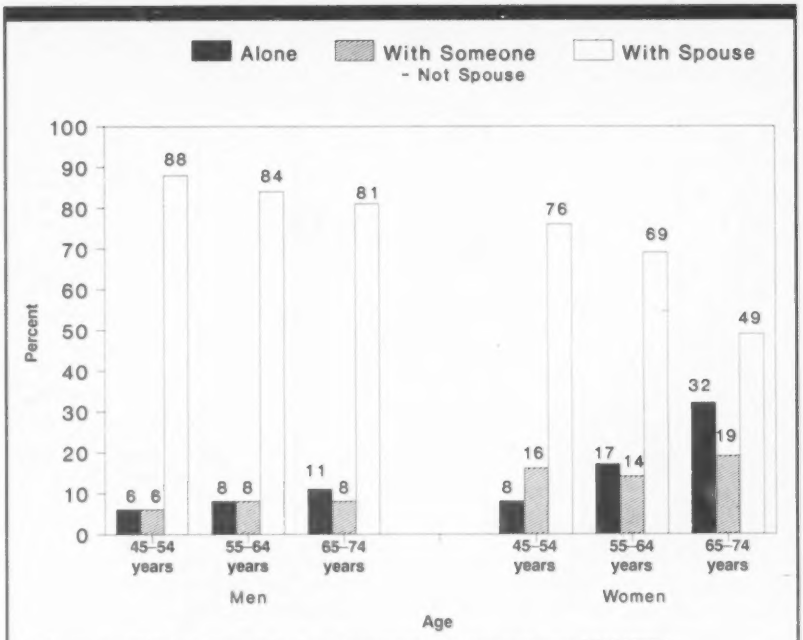

Figure 1—Distribution of living arrangements by age and sex: NHANES I.

Results

Distribution of Living Arrangements

The percentage of persons married and living with a spouse decreased with increasing age (Figure 1), but the decrease was greater for women than for men. Among men who were not married and living with a spouse, approximately equal proportions lived alone as lived with someone other than a spouse. For women, the proportion living alone increased with age.

Association of Living Arrangements with Survival

Men who lived alone or with someone other than a spouse had significantly shorter survival times compared with those living with a spouse (Table 2). The magnitude of the relative hazard of dying was similar within each age group for men living alone and men living with someone other than a spouse. The age-adjusted relative hazard of dying was highest in the youngest age group, 45 to 54 years, and decreased somewhat with increasing age (Table 2). For women, there was a weak association of living arrangements with survival only for those aged 45 to 54 years old (Table 2).

The Role of Chronic Medical Conditions, Health Behaviors, and Sociodemographic Characteristics

Chronic conditions. The presence of chronic conditions at NHANES I decreased survival time in each age-sex group (data not shown). However, adjusting for the number of chronic conditions did not reduce the association of living arrangements with survival (Table 2); this is likely due to the lack of association of chronic conditions with living arrangements (data not shown). Nor was the association of living arrangements with survival reduced when we adjusted individually for each of the nine categories of chronic conditions (data not shown).

Health behaviors. Behavioral variables did not appear to have a major influence on the association of living arrangement with survival, except among men aged 55 to 64 years who were living alone (Table 2). Among the behavioral variables examined, physical activity resulted in the largest reduction in the relative hazard. Adjusting additionally for number of chronic conditions did not change the magnitude of the relative hazards. We also examined the role of self-reported recreational activity in accounting for the association of living arrangements with survival. The relative hazards adjusting for recreational activity (data not shown) were similar to those in Table 2 adjusting for nonrecreational activity.

Sociodemographic characteristics. For men, adjusting for race, education, and income individually did not substantially reduce the association of living arrangements with survival (Table 2). However, in the 45- to 54-year-old group, adjusting for employment substantially reduced the relative hazards when both men living alone and those living with someone other than a spouse were compared with those living with a spouse (Table 2). Adjusting additionally for number of chronic conditions produced relative hazards of death that were similar to those adjusted solely for employment and age (relative hazard [RH] 1.9, confidence interval [CI] 1.1, 3.4 for those living alone; and RH 1.6, CI 0.9, 2.7 for those living with others). With simultaneous adjustment for all variables, living arrangements among men were still marginally associated with survival.

For women aged 45 to 54 years, adjusting for race and income reduced the relative hazard for those living with someone other than a spouse compared with those living with a spouse (Table 2), whereas adjusting for education or employment did not. Adjusting simultaneously for race, income, age, and number of chronic conditions produced relative hazards similar to those produced when adjusting only for age and race or age and income (data not shown). Because of concern about the impact of living arrangements on older, low-income women, we examined the impact of living arrangements on survival for five different income strata in women aged 65 to 74 years. The magnitude of the relative hazards for both women living alone and those living with

[a] All analyses controlled for age within each age group.
Note. RH = relative hazard; CI = confidence interval.

others was very similar across the income strata, and the interaction between income and living arrangements was statistically nonsignificant ($P = .60$).

Discussion

Our analyses were predicated on concern about the effects of living alone on the health and mortality of older adults. Although we did not find that the many women aged 65 to 74 years who lived alone were at higher risk of death than were women their age who were married—this finding being consistent with evidence from 1966–1968 US death and census data[5]—our analyses were restricted to women under 75 years of age. Among women over age 75, the impact of living alone on survival may be different. It is important to study persons aged 74 years and older because 40% of them live alone.[1]

There is growing evidence to suggest that older women living alone are not disadvantaged in terms of their social contacts,[30] mental health,[31,45] physical and functional health,[30,31] or dietary status.[33-35] Our findings also suggest that they are not disadvantaged in terms of survival. In addition, we did not find that older, low-income women living alone had poorer survival than higher-income women living alone. However, we used a measure of current income in these analyses and did not have measures of lifelong income, which may be more important for survival.

We did not find any evidence to suggest that living arrangements have an additional influence on mortality beyond marital status. Men aged 65 to 74 years who lived alone were at slightly higher risk of death than those who were married, as were those who lived with someone other than a spouse. The higher risk of mortality for older men living alone is consistent with results from previous studies of US census data,[5] Swedish men,[46] and widowed men in Washington County, Maryland.[13]

It is somewhat surprising that living with others did not offer a protective effect compared with living alone, given the results of various studies suggesting the importance of social support for decreased mortality.[21,47,48] However, it is possible that any advantage in this group that

comes from social support may be offset by the poor health that requires living with someone. We did not find that persons living with a nonspouse had more chronic conditions than those living alone, but there may be some differences in other aspects of health or functioning that may be related to increased mortality for this group.

We observed a somewhat stronger association of living arrangements with survival for middle-aged adults than for older adults, particularly for men, suggesting the possibility that the importance of living arrangements as a risk factor for mortality decreases with age. Attenuations in the magnitude of the associations of risk factors with survival in older age have been reported for marital status[5,21] as well as for other mortality risk factors.[21,22,49] It is possible that this attenuation is due to selective survival of the fittest as one ages.[21] It is also quite likely that the impact of living arrangements on health and mortality changes across the adult life cycle. For example, using data from the Alameda County Study, Seeman and colleagues[8] report that marital status assumed primary importance for those younger than 60 years old; however, ties with close friends and/or relatives assumed greater importance for those aged 60 years and older.

Although sociodemographic characteristics and health behaviors are known to affect mortality,[19,20,22] we observed only four of the variables (employment status, physical activity, race, income) to account, at least in part, for the association of living arrangements with survival, and then only in certain age and sex subgroups. Employment status was the primary variable associated with both living arrangements and survival for men aged 45 to 54 years. Those who were not working at baseline were at a substantially higher mortality risk than those who were working. We did not find that poorer health status in terms of chronic medical conditions accounted for this higher risk. However, it is possible that some other measures of health status, social support,[50] mental health, or behavioral characteristics not examined in this study may confound this association. In analyses not shown here, excluding men who died in the first 2 years of follow-up, the relationship between living arrangements, employment status, and survival did not change, indicating that the association of employment status with survival time was not due to imminent death in those men aged 45 to 54 years who were unemployed.

Previous studies have reported that controlling for baseline health status does not explain the higher mortality of those living alone[46] or unmarried.[51] Likewise, controlling for the number of chronic medical conditions present at NHANES I did not account for our observed association of living arrangements with mortality. However, the measures available to define health status on the full NHANES I sample were limited and did not include measures of duration or severity of the chronic conditions or physical functioning. More comprehensive measures of health status were available in the smaller, detailed component of the sample, but the small number of deaths in this subsample precluded meaningful analysis.

Interim changes in living arrangements between NHANES I and the follow-up may have obscured existing relationships between living arrangements and survival. However, the survival curves for living arrangements within age and sex groups conformed to the proportional hazards assumption throughout the follow-up period, including the early period when living arrangements were least likely to have changed.

By imputing survival times using several different imputation schemes, we investigated the possibility of nonresponse bias resulting from the exclusion of persons not traced in the NHEFS 1982–1984. Extreme assumptions regarding the survival time of persons lost to follow-up (very short survival for married persons, very long survival times for those not married) did not appear to influence our findings.

Additional cohort studies are needed that examine relationship, age, and gender of household members, as well as examine the dynamics of change in marital status and living arrangements in relation to mortality. It is also important to study the length of time in a specific living arrangement to address whether changes in marital status and living arrangement have acute effects leading to death or comprise a chronically stressful situation affecting health and mortality over time.

In conclusion, we found a stronger pattern of association between living arrangements and survival for men than for women, and for middle-aged men than for older men. There was no additional survival advantage for persons who lived with someone other than a spouse compared with those living alone, and—particularly for men—the critical factor for survival was the presence of a spouse. □

Acknowledgments

This work was supported by grant 5R37 AG05284 from the National Institute on Aging. Preliminary findings in this report were presented at the 118th meeting of the American Public Health Association in New York City on October 4, 1990. The authors wish to thank Dr. Walter Ettinger for gerontological advice, David Lein and John Barclay for assistance with data processing, and Christine Choy for assistance with preparation of the manuscript.

Readmission after Surgery in Washington State Rural Hospitals

H. Gilbert Welch, MD, MPH, Eric H. Larson, MS, L. Gary Hart, PhD, and Roger A. Rosenblatt, MD, MPH

ABSTRACT

Background. Because of concern about the quality of care in rural hospitals, we examined readmission following four surgical procedures commonly performed in Washington State rural hospitals: appendectomy, cesarean section, cholecystectomy, and transurethral prostatectomy.

Methods. In a retrospective cohort study, we identified all patients discharged after receiving one of the foregoing procedures using the statewide hospital discharge database. Readmissions to any hospital in the state within 7 or 30 days of discharge were also identified.

Results. During the 2-year period examined, there were no significant differences in readmission rates for surgeries performed in rural and urban hospitals, although the readmission rates for all four procedures were nominally lower in rural hospitals. Logistic regression analyses that controlled for factors that influence readmission did not change these results.

Conclusions. Investigating readmission rates following common surgeries, we found no evidence of low-quality surgical care in Washington State rural hospitals. Early readmission is an imperfect marker for poor surgical outcome, however, and other proxies for quality remain to be examined. (*Am J Public Health.* 1992;82:407–411)

Introduction

Rural hospitals account for almost half of all short-stay nonfederal hospitals in the United States.[1] They facilitate access to basic medical services in geographically isolated areas. Equally important is their role of providing emergency care, particularly for cases of accidental injury,[2] to residents who would otherwise experience long delays in traveling to distant facilities. The finding that 10% of the nation's rural hospitals have closed during the past decade has therefore been the subject of considerable concern.[3]

One cause of rural hospital closures has been an increasing centralization of medical services into urban hospitals. This phenomenon is accelerated by assertions that small rural facilities deliver care of inferior quality.[4,5] Rural residents may be acting on this belief when deciding to seek elective care in large urban hospitals.[6,7] Because diminished use undermines the fiscal viability of any hospital, assertions of low-quality care in rural hospitals may threaten their ability to survive. Unfortunately, this area has been inadequately studied.[2]

To investigate one aspect of quality, we examined patients who underwent any of four surgical procedures frequently performed in Washington State rural hospitals. We tested the hypothesis that rural hospitals had the same readmission rates, following these surgeries, as their urban counterparts. Readmission rates are an often used, although imperfect, proxy for quality.[8–10] Readmissions to any Washington State hospital within 7 or 30 days of being discharged were analyzed.

Methods

Readmission Data

Data were obtained from the Washington State Commission Hospital Abstract Reporting System (CHARS). The CHARS database used in this analysis includes information on all discharges from Washington State hospitals (excluding newborns) occurring during calendar years 1987 and 1988. The methodology used to link the 925 309 discharge records into 636 328 individual patient records has been described elsewhere.[11] Patients transferred from one hospital to another were not counted as readmissions.

Definition of Rural

Although there are many schemes that differentiate rural and urban areas,[12] all are imperfect attempts to dichotomize a multidimensional attribute. Recognizing this problem, we chose the current criteria of the Washington State Department of Health for defining rural hospitals (V. Gibbs, personal communication, December 1989). Rural hospitals have been de-

This paper was submitted to the journal December 11, 1990, and accepted with revisions June 10, 1991.

TABLE 1—Discharge Diagnosis-Related Groups Selected for Analysis

Procedure Description (ICD-9 procedure code)	Diagnosis-Related Group
Appendectomy (47.0)	
With complicated principal diagnosis with CC	164
With complicated principal diagnosis without CC	165
Without complicated principal diagnosis with CC	166
Without complicated principal diagnosis without CC	167
Cesarean section (74.1)	
With CC	370
Without CC	371
Cholecystectomy (51.22)	
With common duct exploration with CC	195
With common duct exploration without CC	196
Without common duct exploration with CC	197
Without common duct exploration without CC	198
Transurethral prostatectomy (60.2)	
With CC	336
Without CC	337

Note. Comorbid conditions must exist prior to the admission, while complications must develop during the hospitalization. CC = complications and/or comorbidity; ICD-9 = *International Classification of Diseases*, 9th version.

fined as those that are located in counties with a population of less than 200 000 and that are more than 5 miles from the boundaries of a city or city cluster with a population of more than 25 000. Designated hospitals are generally much farther away from cities, but the criteria were fashioned to allow specific hospitals near small cities in rural landscapes to qualify. Forty-four hospitals in Washington State are designated as rural using these criteria, while the other 62 hospitals are considered urban.

Selection of Common Surgical Procedures

Using the primary *International Classification of Diseases*, 9th version (ICD-9), procedure code, we identified the 10 most common surgical procedures performed in Washington's rural hospitals. Five of these procedures involved routine peripartum care: artificial rupture of membranes, episiotomy, spontaneous vaginal delivery, repair of obstetrical laceration, and circumcision. The other 5 involved more complex procedures and were selected for analysis because of their higher a priori potential for complications. One procedure, hysterectomy, was excluded because the two distinct surgical approaches (abdominal and vaginal) were found to be differentially performed in rural and urban areas. Two of the four procedures analyzed here are predominantly elective: cholecystectomy and transurethral prostatectomy. Two are more likely to be nonelective: appendectomy and cesarean section.

Selection of Study Population

All patients undergoing operations in Washington State hospitals after January 31, 1987, were eligible for inclusion in the analysis. Patients with previous admissions were excluded from study. Additionally, study patients had to be discharged (after surgery) on or before November 15, 1988, to be eligible. This end date allowed for all subsequent admissions within 30 days to be captured, provided they were less than 2 weeks in duration.

The analysis was restricted to patients with one of four ICD-9 primary operative procedure codes: appendectomy (47.0), cesarean section (74.1), cholecystectomy (51.22), or transurethral prostatectomy (60.2).[13] The analysis was further restricted to patients whose discharge was assigned one of the diagnosis-related groups (DRGs) listed in Table 1. This eliminated patients for whom the procedure was a relatively insignificant portion of hospitalization (e.g., a patient undergoing induction chemotherapy for leukemia who requires an appendectomy). This restriction eliminated 2.6% of the appendectomy patients, 0.2% of the cesarean section patients, 3.4% of the cholecystectomy patients, and 9.4% of the prostatectomy patients. No detectable rural–urban differences in in-hospital mortality were found for patients in these DRGs. The 60 patients who died within the hospitalization during which they were operated on (6 at rural hospitals, 54 at urban hospitals) were excluded from further analysis.

Analysis of Readmissions

Readmission was defined as a second admission, to any hospital in Washington State, within 7 or 30 days of discharge. Crude 7-day and 30-day readmission rates were compared in rural and urban hospitals. In addition, the risk of readmission for patients operated on in rural hospitals relative to those operated on in urban hospitals was calculated. Confidence intervals surrounding the relative risk estimates were calculated using the standard error approximation.[14]

The initial findings for each surgery were verified through analysis of more homogeneous subgroups (e.g., analysis of appendectomies was restricted to patients between 10 and 40 years of age, analysis of cesarean sections was restricted to patients between 20 and 30 years of age, and analyses of all procedures were restricted to patients with private insurance). Urban and rural differences were tested via the standard χ^2 corrected for continuity test and t test. In addition, multiple logistic regression was used to simultaneously control for factors other than the rural or urban location of surgery that are thought to influence readmission rates. The factors controlled for from the discharge abstracts included patient age and sex, payor type (e.g., Medicaid), emergency admission, length of stay, and presence of comorbid conditions.

This study is basically descriptive and includes the population of relevant surgeries and readmissions for a 2-year period in Washington State. Expanding the study temporally or geographically would increase the power of the analyses but would obscure precisely which population was being examined. The overall power of the study when the four surgeries are aggregated is .75 for a difference of 3 readmissions per 1000 admissions, but is lower for each of the surgeries taken separately. However, it should be remembered that study results are not extrapolated beyond their descriptive limits and that all relevant cases have been included in the analyses. Thus, the study's results stand on their own as a description of Washington State for 2 years but must be viewed cautiously if extrapolated further.

Results

During the study period, approximately 12% of all hospital discharges in Washington came from the state's 44 rural hospitals. These 44 hospitals were responsible for 10% of all procedures performed.

TABLE 2—Diagnoses Accounting for More than 5% of 7-day Readmissions for Four Surgical Procedures

Procedure	DRG	DRG Description	Readmissions, %	Cumulative %
Appendectomy				
	418	Postoperative infection	28	28
	415	OR procedure for infection	26	54
	183, 184	Gastroenteritis/digestive disorders	15	69
	453	Complications of treatment	5	74
Cesarean section				
	376	Postpartum complications	68	68
	377	Postpartum complications, to OR	8	76
Cholecystectomy				
	418	Postoperative infection	12	12
	182, 183	Gastroenteritis/digestive disorders	12	24
	452, 453	Complications of treatment	11	35
	188, 189	Other digestive system diagnoses	11	46
	204	Pancreatic disorders	6	52
	442	Operation for hemorrhage/repair	6	58
Transurethral Prostatectomy				
	452, 453	Complications of treatment	36	36
	331	Other kidney/urinary tract diagnoses	6	42

Note. DRG = diagnosis-related group; OR = operating room. Paired DRGs (188, 189 and 452, 453) combine patients with and without complications and/or comorbidities (CC). DRGs 182 (without CC) and 183 (with CC) are for patients over age 17; DRG 184 is for patients 1–17 years of age.

7-day relative risk (95% confidence interval)	.73	(0.42, 1.27)	.71	(0.39, 1.29)	.60	(0.35, 1.03)	.74	(0.45, 1.22)
30-day relative risk (95% confidence interval)	.76	(0.52, 1.10)	.82	(0.56, 1.20)	.95	(0.73, 1.23)	.86	(0.65, 1.15)

[a]For cesarean section, age adjusted rates are expressed as procedures per 1000 deliveries.
*$P < .05$, intrasurgery rural/urban comparison.
**$P < .01$, intrasurgery rural/urban comparison.

Of the four surgical procedures analyzed here, 14% were performed in rural hospitals.

The most common 7-day readmission diagnoses following each surgery are listed in Table 2. The dominance of diagnoses such as postoperative infection, digestive disorders, and complications of treatment in readmitted patients indicates that readmission within the 7-day period generally reflects complications of surgery. Careful examination of less frequent readmission diagnoses revealed additional conditions compatible with complications from recent surgery.

Procedure-specific data are shown in Table 3. With the exception of cesarean section, age–sex-adjusted procedure rates are higher for the population living in the service areas of rural hospitals. Patients hospitalized in rural hospitals were significantly more likely to be uninsured or receive Medicaid (except in the case of transurethral prostatectomy, where the majority of patients are eligible for Medicare). For two procedures (appendectomy and cesarean section), the mean length of stay for patients hospitalized in rural hospitals was significantly shorter than for those hospitalized in urban centers; for the remaining two procedures, no difference in length of stay was observed.

Figure 1 displays the 7-day readmission rates for each procedure in both rural and urban hospitals. Regardless of the procedure examined, readmission rates follow-

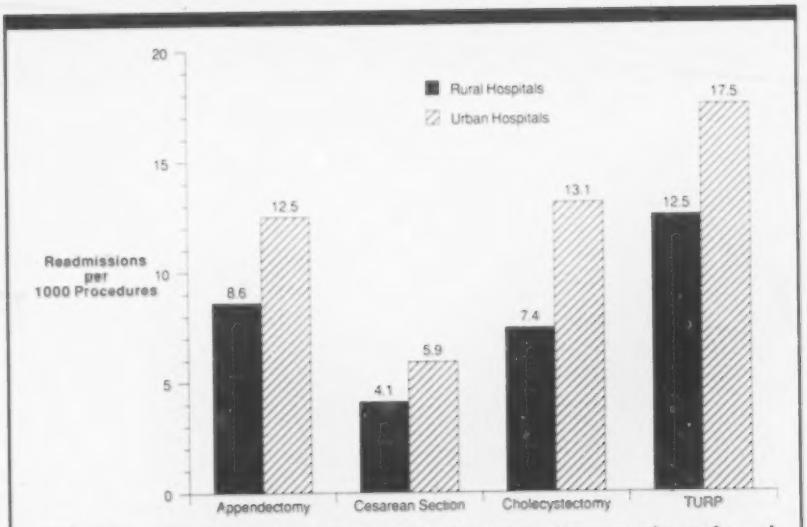

FIGURE 1—Seven-day readmission rates following four routine surgeries performed in Washington State rural and urban hospitals (1987–1988). TURP = transurethral prostatectomy.

ing surgeries performed in rural hospitals were lower than for those performed in urban hospitals. The 7-day relative risk of readmission for patients operated on in rural hospitals (shown in Table 3) ranged from .60 for cholecystectomy to .74 for transurethral prostatectomy. Thirty-day relative risk estimates were somewhat higher and ranged from .76 for appendectomy to .95 for cholecystectomy. Relative risk estimates were consistently below one in analyses of more homogeneous subgroups.

To further examine the potential confounding influence of case mix, a logistic regression analysis was performed. This analysis was designed to test, for each of the four surgeries, whether the finding of lower readmission rates following surgery in rural hospitals would persist after simultaneously controlling for other factors that influence rehospitalization. The variables included in the regressions were patient age, sex, payor type (e.g., Medicaid/self-pay, Medicare, and other insurance), emergency admission, length of stay, and number of comorbid conditions. Alternative functional forms of several of these factors were tested for both 7-day and 30-day readmissions. Many of the control variables were significantly associated with readmission. Although not statistically significant, the regression coefficient for surgery in rural hospitals remained negative for all procedures.

Discussion

We investigated four common surgeries in Washington State hospitals and found that rural hospitals did not have elevated readmission rates. In fact, for each of the four procedures, 7-day readmission rates for rural hospitals were consistently lower than those in urban hospitals, although not significantly so. When all readmission data are pooled, however, the statistical power of this investigation to detect significantly different rural readmission rates (were they to exist) increases our confidence in its major finding. Furthermore, this descriptive study includes every event for a 2-year period in the population of interest. Expanding the study in time or to other locales might make the conclusion more certain but would obscure precisely which population was being studied.

Readmission rates following surgery are an indirect measure of quality. The diagnoses commonly observed during readmission (postoperative infection, digestive disorders, and complications of treatment), however, suggest that readmission generally reflects complications of surgery. Some patients develop complications immediately following surgery and remain hospitalized longer, rather than being discharged and readmitted. This may reflect important quality problems that cannot be identified using readmission as a marker. The use of logistic regression analysis, however, controlled for this potentially confounding variable.

The possibility that case-mix differences explain outcome differences is always a concern in investigations of this type. There are two major reasons one might posit that Washington's urban hospitals had "sicker patients." One possibility is that sicker patients living in rural areas tend to have their surgery done in urban hospitals. Yet, removing rural residents whose surgery was performed in urban hospitals had a minimal effect on the analysis. A second possibility is that urban hospitals serve a more disadvantaged population than do rural hospitals. Inner-city patients may be discharged to a more hostile home environment, making readmission more likely. However, eliminating all Medicaid, self-pay, and charity patients (the CHARS data contain no information on patient race, income, or education) from the patient population studied or controlling for factors such as age, payor type, and comorbid conditions also had minimal effect. To the extent case mix can be imputed from the discharge database, these analyses suggest that it is not an important confounder in this study.

Finally, it is possible that our findings reflect differences in patient or provider behavior, obscuring real quality differences. Rural patients, for example, may be more hesitant than urban patients to seek care for postsurgical problems. It is not possible to ascertain the effect that patient attitudes might have on the results. Alternatively, rural providers may be more likely to treat postsurgical problems on an outpatient basis and have a higher threshold for readmission than urban providers. However, the extended distances that patients often travel to rural hospitals suggest that rural providers would be more likely to display the opposite behavior.

For these four common surgical procedures, it is hard to argue that Washington State's rural hospitals performed poorly in comparison to their urban counterparts. In nominal terms, rural readmission rates were, in fact, lower. The extent to which our findings extend to other commonly provided surgical services is unknown. Although these data are from a limited geographic region and may not reflect patterns elsewhere, similar work has demonstrated that high-quality obstetrical care can be provided in rural settings.[15,16] Our study suggests that these four routine surgical procedures can be provided at rural hospitals with a quality comparable to urban facilities. This kind of information can help administrators and physicians in rural hospitals define a range of services that enhances both fiscal performance and operator proficiency without compromising quality. More important, it serves to discredit the general perception that rural hospitals provide inferior care. □

New Pathways in Epidemiology to Be Explored in Sydney

The International Epidemiological Association announces the following meeting:

New Pathways in Epidemiology
Thirteenth Scientific Meeting
University of Sydney, Australia
September 26 to 30, 1993

This exciting opportunity to participate in a major international scientific meeting will provide an opportunity to examine new pathways in global health, clinical practice, environmental issues, health services management, and methodology and also to savor Sydney in the Southern Hemisphere spring.

If you would like to be included on the conference mailing list, please send contact details—your name, title, affiliation/institution, and the best address for reaching you—to IEA Conference Secretariat, PO Box 746, Turramurra 2074 NSW, Australia.

The Behavioral Risk Factor Survey and the Stanford Five-City Project Survey: A Comparison of Cardiovascular Risk Behavior Estimates

Christine Jackson, PhD, Darius E. Jatulis, MS, and Stephen P. Fortmann, MD

ABSTRACT

Background. Nearly all state health departments collect Behavioral Risk Factor Survey (BRFS) data, and many report using these data in public health planning. Although the BRFS is widely used, little is known about its measurement properties. This study compares the cardiovascular risk behavior estimates of the BRFS with estimates derived from the physiological and interview data of the Stanford Five-City Project Survey (FCPS).

Method. The BRFS is a random telephone sample of 1588 adults aged 25 to 64; the FCPS is a random household sample of 1512 adults aged 25 to 64. Both samples were drawn from the same four California communities.

Results. The surveys produced comparable estimates for measures of current smoking, number of cigarettes smoked per day, rate of ever being told one has high blood pressure, rate of prescription of blood pressure medications, compliance in taking medications, and mean total cholesterol. Significant differences were found for mean body mass index, rates of obesity, and, in particular, rate of controlled hypertension.

Conclusions. These differences indicate that, for some risk variables, the BRFS has limited utility in assessing public health needs and setting public health objectives. A formal validation study is needed to test all the risk behavior estimates measured by this widely used instrument. (*Am J Public Health.* 1992;82:412–416)

Introduction

Nearly all state health departments now collect Behavioral Risk Factor Survey (BRFS) data,[1] and many report using BRFS data to set state objectives, plan statewide health education programs, and support public health legislation.[2,3] But although the BRFS is widely used, little is known about its measurement properties. The Centers for Disease Control has published annual reports of BRFS prevalence estimates for selected states[4,5] and national prevalence estimates from pooled data for cigarette smoking,[6] overweight,[7] and alcohol use.[8] A study of the test-retest reliability of the BRFS reported estimates that were generally 0.60 or greater for cardiovascular risk behaviors other than dietary behaviors, for which lower estimates were found.[9] Studies comparing BRFS estimates to other measures are limited to one study that found that, for selected risk behaviors, total population estimates from the combined 1981–1983 BRFS data were similar to those from national surveys conducted between 1979 and 1980,[10] and to a second study that found that most age- and sex-specific estimates for smoking and binge drinking were comparable for the BRFS and an in-person interview.[11]

The present study builds on this previous work by comparing the BRFS cardiovascular risk behavior prevalence estimates with estimates from the Stanford Five-City Project's random household survey (FCPS), which is the principal evaluation instrument of the Stanford Five-City Project.[12] Importantly, the FCPS includes physiological comparison measures for cigarette smoking, blood pressure, blood cholesterol, height, and weight. These measures currently provide the best estimates of risk and so can be used as benchmarks against which the BRFS estimates can be compared. This study also compares BRFS variables not previously evaluated, including smoking rate, body mass index (BMI), and total cholesterol.

Method

Study Samples

Both the BRFS and FCPS samples were drawn from the same four northern California communities participating as education or control cities in the Stanford Five-City Project[12] (see Table 1).

The BRFS is the first of three biennial random telephone surveys planned for the Five-City Project. The Waksberg[13] random-digit dialing method was used to generate the probability sample, and a detailed description of the sampling method and contact protocol for this study is available elsewhere.[14] The total sample included 2360 individuals, of whom 1588 (67%) were aged 25 to 64, spoke English, and were included in the present study. A response rate of 83% was obtained for the total sample. Because confirmation of the telephone number and city of residence were the only data obtained from nonre-

This paper was submitted to the journal August 31, 1990, and accepted with revisions June 10, 1991.

spondents, it is not possible to calculate a response rate for the 25- to 64-year-old subsample.

The FCPS is the fourth biennial random cross-sectional survey conducted by the Five-City Project, and a detailed description of the survey method is available.[12] The total sample included 2378 individuals, of whom 1512 (64%) were aged 25 to 64, spoke English, and were included in the present study. The response rate was 56% for the total sample and 61% for the 25- to 64-year-old subsample.

Measures

Components of the BRFS and FCPS were selected for comparison if an interview measure from the BRFS and a physiological measure from the FCPS purport to measure the same variable (e.g., current smoking status, weight), or if interview questions from the BRFS and FCPS have the same or similar wording and so appear to measure the same variable (e.g., number of cigarettes smoked per day, compliance in taking blood pressure medications). An abbreviated description of the comparison is presented in Table 2; a detailed description of the physiological assessments used by the Five-City Project is available,[12] and a copy of the wording of the BRFS and FCPS interview measures compared in this study may be requested from the first author.

Analyses

Continuous measures for the two surveys were compared using *t* tests; when the sample variances were found to be significantly different, a separate variance *t* test was used. The chi-square test was used to evaluate significance for most dichotomous outcomes.

To control for possible effects of demographic differences between samples, adjusted total sample estimates were also computed for each outcome. Adjusted values for the continuous outcomes were found using analysis of covariance; logistic regression was used for categorical outcomes.[20]

Results

Sample Characteristics

Compared with the FCPS sample, the BRFS sample had more females (a result consistent with the generally higher rate of refusal among males for telephone surveys)[21] and a lower mean age, but the same mean educational level (see Table 1).

TABLE 1—Survey and Sample Characteristics of the Behavioral Risk Factor Survey (BRFS) and the Five-City Project Survey (FCPS)

	BRFS (1987)	FCPS (1986)	
Geographic area	education and control cities of the Five-City Project	education and control cities of the Five-City Project	
Sample method	random-digit dialing	random household	
Survey method	telephone interview	face-to-face interview; physiological assessment	
Eligibility	one person aged 18 or older	all persons aged 12–74 in household	
Response rate	83% (total sample) NA (ages 25–64)	56% (total sample) 61% (ages 25–64)	
Sample size	2360 (total sample) 1588 (ages 25–64)	2378 (total sample) 1512 (ages 25–64)	
Sample demographics			*P*
% Male	41.6 (n = 660)	46.2 (n = 698)	
% Female	58.3 (n = 926)[a]	53.8 (n = 814)	.01
% Age 25–34	40.2 (n = 638)	34.2 (n = 517)	
% Age 35–44	28.1 (n = 446)	28.2 (n = 427)	
% Age 45–54	15.6 (n = 248)	18.8 (n = 284)	
% Age 55–64	16.1 (n = 256)	18.8 (n = 284)	.002
Mean age	40.1 (SD = 11.4)	41.5 (SD = 11.5)	.001
% <12 years education	9.4 (n = 150)	8.9 (n = 135)	
% 12 years education	23.0 (n = 365)	25.9 (n = 391)	
% 13–15 years education	35.3 (n = 560)	29.7 (n = 449)

Mean years education	14.2 (SD = 2.2)	14.1 (SD = 2.9)	.12

Note. SD = standard deviation of a sample.
[a]Gender data missing for two respondents.

Cigarette Smoking Estimates

The BRFS and FCPS provide comparable estimates of current smoking rates and mean number of cigarettes smoked per day, with none of the between-survey differences being statistically significant (see Table 3). The results are less consistent for rates of heavy smoking. Although the FCPS estimate is significantly higher for the total sample comparison, most of this effect is attributable to the City 3 subsample, with the remaining cities having comparable estimates of heavy smoking. As this measure is identically worded on both surveys and there are no known events or method differences unique to City 3, it is not clear why this discrepancy occurred.

Blood Pressure Estimates

Generally comparable estimates were found for the measures of ever being told one has high blood pressure and of being prescribed blood pressure medications (Table 4). Although significant between-survey differences were found for some cities, neither survey is systematically higher or lower and the differences between the total sample estimates are not significant.

The BRFS and FCPS also measure compliance in taking blood pressure medications (data not shown). Both surveys found high levels of compliance, with 95% and 93% of the BRFS and FCPS samples, respectively, reporting that they always or almost always take their blood pressure medications. While these estimates indicate that the surveys provide comparable estimates of compliance, they also indicate that both surveys probably overestimate actual compliance rates. In a recent review of medical compliance studies, for example, Kaplan and Simons[22] report that most studies find at least 33% noncompliance for therapeutic regimens.

Of all the outcomes compared in this study, the between-survey differences are largest for estimates of controlled hypertension among individuals with hypertensive medications prescribed. The magnitude of the between-survey differences, ranging from 16% to 62%, suggests that a true measurement difference exists and raises some concern about the utility of this BRFS item. The 1987 California BRFS* found that 91% of hypertensives aged 25 to 64 report having their high

TABLE 2—Comparison Measures from the Behavioral Risk Factor Survey (BRFS) and the Five-City Project Survey (FCPS) for Comparable Variables

Variable	BRFS	FCPS
Cigarette smoking	(1) self-reported smoking status	self-reported smoking status verified by thiocyanate and carbon monoxide test[15]
	(2) self-reported number of cigarettes smoked per day	same
	(3) percent of heavy smokers, defined as those reporting 25 or more cigarettes smoked per day	same
Hypertension	(4) self-reported hypertension measured as ever being told by a doctor or other health professional that one has high blood pressure	same
	(5) self-reported medical prescription for hypertension control	self-reported medical prescription for hypertension control, verified by interviewer inspection of medications and recording of drug names
	(6) self-reported compliance in taking hypertension medications	same
	(7) self-reported blood pressure status as normal or under control	normotensive status, defined as systolic pressure < 140 mm and diastolic pressure < 90 mm, using automated blood pressure readings[16,17]
Overweight	(8) mean BMI, using self-reported weight and height	mean BMI, using weight measured with a balance scale and height measured with a metal rule
	(9) same BMI values as the FCPS, but based on self-reported height and weight	percent with obese BMI values, defined as being more than 130% of the mean BMI for males (BMI > 28.08) and females (BMI > 27.56)[18]
Cholesterol	(10) mean self-reported total cholesterol value	mean plasma cholesterol measured with the standardized Lipid Research Clinics protocol[19]

Note. BMI = body mass index.

blood pressure under control, an indication that the 89% estimate reported by the present sample is reliable. Considering the factors that could affect responses to the BRFS measure, it is most likely that the self-report format results in inflated estimates of control. It is possible, for example, that BRFS respondents who had lowered *either* their systolic or their diastolic pressure reported this as gaining control. In contrast, FCPS respondents must have had *both* systolic and diastolic pressures below physiological cut-points to be counted as having their high blood pressure under control. Overall, the data suggest that the BRFS self-report item actually measures the perception that one's blood pressure is under control and that the prevalence of this perception greatly exceeds real levels of controlled hypertension.

BMI Estimates

The BRFS estimates for both mean BMI and percent obese BMI were consistently and significantly lower than the FCPS estimates (see Table 5). The differences in mean BMI ranged from –1.0 to –2.2, with the –1.5 difference between the total sample estimates representing approximately a 10-lb difference in weight. Such underreporting of weight is to be expected, but the magnitude is larger here than has been observed elsewhere.[23,24]

Cholesterol Estimates

Before comparing the survey estimates of mean total cholesterol, we note that only 9% (n = 149) of the total BRFS sample reported ever being told a cholesterol value *and* were able to report a cholesterol value. Although this BRFS sample is relatively small, the mean cholesterol values are well within the normative range, and a demographic breakdown of the sample (not shown) reveals that expected increases in knowledge of one's cholesterol come as age and level of education increase, and that increases in mean total cholesterol come with age. Thus, despite its small size, this BRFS sample warrants cautious comparison with the FCPS sample. As shown in Table 5, the surveys produced comparable estimates of mean total cholesterol.

Adjusted Estimates

Adjusting the total sample estimates for age, sex, and education had no effect on the significance of the between-survey differences and had little effect on the actual prevalence estimates. (Because of the large difference in sample size, adjusted estimates were not computed for total cholesterol.) Significant survey × age or survey × education interactions were found for some outcomes. Examination of the age- and education-stratified estimates for all outcomes (not shown) indicate that the significant interactions were generally due to one age or educational subgroup being different from the rest, rather than to a complete reversal in the pattern of results.

Discussion

Comparing the cardiovascular risk behavior prevalence estimates for the total BRFS and FCPS samples, we found substantial between-survey agreement for several variables: current smoking rate, number of cigarettes smoked per day, rate of ever being told one has high blood pressure, rate of prescription of blood pressure medications, compliance in taking medications, and mean total cholesterol. These results indicate that, at least in large samples, the BRFS provides accurate estimates for these cardiovascular risk variables. The results also indicate that two of these variables, while producing comparable estimates, have other limitations. First, the estimates of compliance in taking blood pressure medications were found to be quite high and probably overestimate actual compliance rates. Second, only a small proportion of the BRFS sample could report a cholesterol value, indicating that, while this measure is useful in estimating knowledge of cholesterol, it has limited utility in estimating mean total cholesterol for a population.

Comparable between-survey estimates were not found for the other risk behavior variables: prevalence of controlled blood pressure, mean BMI, and prevalence of obesity. For these variables, the total sample comparisons and most of the city-specific comparisons were statistically significant and of a magnitude likely to affect public health planning decisions. Of particular concern for those using BRFS data for needs assessment and program planning are the overestimation of controlled hypertension and the underestimation of obesity.

Although this study contributes to the measurement information on the BRFS, a formal validation study is needed. Of particular interest are the BRFS dietary and exercise behavior items, which have not been evaluated. Further research is needed to inform those using BRFS data in public health decision-making of the validity of the estimates on which such decisions are based. □

Smokeless Tobacco, Cardiovascular Risk Factors, and Nicotine and Cotinine Levels in Professional Baseball Players

David Siegel, MD, MPH, Neal Benowitz, MD, Virginia L. Ernster, PhD, Deborah G. Grady, MD, MPH, and Walter W. Hauck, PhD

ABSTRACT

Background. The use of smokeless tobacco (ST), which has increased in popularity over the past 2 decades, results in considerable systemic exposure to nicotine. Nicotine might contribute to atherosclerosis by an effect on cardiovascular risk factors.

Methods. The effects of ST use on cardiovascular risk factors and cotinine and nicotine levels were studied in 1061 professional baseball players during spring training in 1988 and 1989.

Results. Of the study participants 477 (45%) were users. ST use was more common among Whites (55%) than among Blacks (29%) or Hispanics (21%), and users reported heavier consumption of alcohol ($p < .001$) and had higher mean serum caffeine levels ($p < .001$) than nonusers. ST users did not differ from nonusers in adjusted levels of systolic and diastolic blood pressure, pulse, and total or HDL-cholesterol. Among ST users, participants using snuff had higher mean serum cotinine levels than those who used chewing tobacco ($p < .001$). There was no association between serum cotinine levels and adjusted levels of any cardiovascular risk factor studied. However, higher diastolic blood pressures were associated with higher mean serum nicotine levels ($p = .02$).

Conclusions. Smokeless tobacco use has at most a modest effect on cardiovascular risk factors in young physically fit men. (*Am J Public Health.* 1992;82:417-421)

Introduction

The use of smokeless tobacco (ST)—oral snuff or chewing tobacco—increased in popularity in the 1970s and 1980s. Approximately 10 million Americans used ST in the past year; 3 million were less than 21 years of age.[1] Among young men, the use of moist snuff has become particularly widespread.[2] Smokeless tobacco use results in considerable systemic exposure to nicotine.[3,4] The results of studies of cigarette smokers have led to concern that nicotine may increase the risk of atherosclerotic vascular disease.[5] Nicotine may contribute to atherosclerosis by affecting lipid metabolism, coagulation, hemodynamic status, or all three. Smokers have higher levels of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) cholesterol and lower levels of high-density lipoprotein (HDL) cholesterol than do nonsmokers.[6-8] Cigarette smoking or the administration of nicotine acutely increases heart rate and blood pressure, although in habitual cigarette smokers blood pressure tends to be lower than in nonsmokers.[9] Circulating leukocytes, primarily neutrophils, are higher in smokers than in nonsmokers, and leukocyte counts return toward nonsmoking levels after smoking cessation.[10,11] Neutrophils may generate oxygen-free radicals and other substances that promote thrombosis, and they may accelerate endothelial cell growth, both of which could contribute to the acceleration of atherosclerotic vascular disease.[5,12] Whether nicotine exposure from ST use has similar effects on lipid metabolism, neutrophils, blood pressure, and heart rate, and thus predisposes to atherosclerotic vascular disease, has not been established.

In studies performed on a research ward, ST use resulted in systemic absorption of nicotine and cardiovascular effects similar to those observed with cigarette smoking.[13] In reports of small numbers of individuals, ST use has been associated with hypertension, perhaps related to ST's salt content or to nicotine-related catecholamine release.[13-15] One recent study reported an association between ST use and elevated levels of total serum cholesterol.[8]

We recently completed a comprehensive study of the health effects of ST use in professional baseball players.[16] A part of the study's purpose was to determine whether ST use was associated with changes in cardiovascular risk profiles. Specifically, we measured blood pressure, heart rate, total serum cholesterol, HDL cholesterol, and white blood cell counts. We also quantitated nicotine intake from ST by measuring plasma nicotine and its metabolite cotinine in plasma.

Editor's Note: See related Commentary by Connolly on page 351.

the first year of the project have been presented elsewhere.[16] We report here detailed findings from the first 2 years of the study on cardiovascular risk factors and nicotine and cotinine levels in the participants.

During February and March of 1988 and 1989, we studied 1061 members of the seven major league professional baseball teams and their associated minor league teams that conduct spring training in the greater Phoenix and Tucson, Ariz, area. All players and coaches on the teams were invited to participate in the study.

After giving informed consent, all participants completed a questionnaire that provided demographic data and information about cigarette smoking and coffee and alcohol consumption. There were only 41 current cigarette smokers and they were excluded from analyses. Detailed information concerning patterns of ST use, including type and brand used most often, was collected. Analyses of type (snuff or chewing tobacco) and brand were based on the type and brand usually used. The amount of ST used was based on the number of cans of snuff or pouches of chewing tobacco reportedly used per week. Because many participants who usually used one type of ST occasionally used the other type, the combined number of hours that tobacco of either type was held in the mouth per day was also calculated. Recency of use was determined as hours since ST was last used.

The participants were classified on the basis of their self-reported ST use as nonusers (those who had never used ST or who had used ST in the past but never more frequently than once a month) and users (those who had used ST within the past week). Former users (those who had used ST more than once a month in the past but had not used ST within the previous month) and infrequent current users (those who had used ST within the past month but not within the past week) were excluded from analyses. For any player for whom we had data from both 1988 and 1989, we used only the data from the year for which the data were most complete. If data from both years were equally complete, 1989 data were used for that player. Data from a total of 477 ST users and 584 nonusers are included in this report.

Blood Pressure and Pulse

After the participants completed the questionnaire, their heart rate and blood pressure were measured twice, several minutes apart, in a sitting position. Systolic blood pressure was recorded at the level when phase 1 Korotkoff sounds were first heard and diastolic blood pressure was recorded at the beginning of phase 5 with the disappearance of sounds. To avoid the effects of physical activity, we included in our analysis of blood pressure and pulse rates only measurements from individuals who had not come to the examination directly from the playing field.

Biochemical Measurements

Blood was drawn to measure total serum cholesterol; HDL cholesterol; nicotine, cotinine, and caffeine levels; and white blood cell count. Biochemical validation of self-reported ST use included measurement of cotinine (the primary metabolite of nicotine) and thiocyanate (a marker of tobacco smoke exposure) by gas chromatography.[17] Low serum cotinine level (<12 ng/mL) together with normal serum thiocyanate levels (<85 mmol/L) was considered biochemical evidence of nonuse of tobacco.[18] This standard, applied in an initial analysis of participants from whom blood was obtained in 1988 and who reported that they neither used ST nor smoked cigarettes, indicated that 95% (357 of 376 for whom blood samples were obtained in 1988) were correctly classified biochemically as nonusers. Given the high accuracy of use status based on self-report and the fact that blood samples were not obtained from all players presented here, the results shown in Tables 1, 2, and 4 are based on self-report. Serum caffeine was measured simultaneously with nicotine and cotinine; 7-ethyl theophylline, 5-methylnicotine, and 1-methyl-5-(2-pyridyl)-pyrrolidine, respectively, were used as internal standards.

Statistical Analysis

Estimated odds ratios were calculated and adjusted for covariates by means of multiple logistic analyses.[19] All logistic analyses were done with the CATMOD procedure on PC-SAS (SAS Institute, Cary, NC) with confidence intervals based on standard errors of the log odds ratios. Significance levels for analyses of covariance were determined with PC-SAS's GLM procedure. The means reported are least squares means, that is, estimates of the means for each use group adjusting for differences between groups in the covariates. For categorical covariates we created the appropriate indicator variables so that the least squares means are distributed around the overall mean, corresponding to the usual method of adjusting for confounding.

Results

Demographic Characteristics

The distribution of current ST users and nonusers by self-reported age, race, educational level, and alcohol consumption is presented in Table 1. Most participants (77%) in both groups were between 20 and 29 years of age and were white (67%). Participants were relatively well educated—94% had graduated from high school and 74% had completed at least some college.

Twenty-four percent reported no alcohol consumption and 7% reported an average of more than two drinks per day. Smokeless tobacco use varied by age; current-week use was reported by 26% of participants younger than 20 years, 49% of those aged 20 to 29 years, and 38% of those aged 30 years and older. Whites were more likely to report ST use during the past week (55%) than Blacks (29%) or Hispanics (21%). Current-week ST users were heavier consumers of alcohol than were nonusers ($P < .001$), and had higher mean serum caffeine levels (512 ng/ml versus 331 ng/ml, data not shown; $P < .001$) when adjusted for age and race.

Of the ST users, 75% used primarily oral snuff, the others chewing tobacco. Among current users of snuff, 70% used Copenhagen, 21% Skoal, and 6% Hawken. Of the chewers, 48% used Levi-Garett and 42% used Redman (data not shown).

Cardiovascular Risk Factors

There were no significant differences between ST users and nonusers in systolic and diastolic blood pressure, pulse, and total or HDL cholesterol levels when adjusted for age, race, alcohol use, and serum caffeine (Table 2). ST users had lower mean white blood cell counts than nonusers ($P < .01$). There were also no significant differences among ST users in systolic and diastolic blood pressure, pulse rate, white blood cell count, and total or HDL cholesterol levels when evaluated by different measures of use—years of use, hours of use per day, and hours since last use (data not shown).

Cotinine, Nicotine, and Caffeine Levels

Serum cotinine measurements were obtained in 230 of the current users. Table 3 presents cotinine levels in relation to type and patterns of ST use. Participants who used snuff had higher adjusted mean serum cotinine than participants who used

chewing tobacco ($P < .001$). Only 1% of the participants who used chewing tobacco, compared with 24% of those who used snuff, had serum cotinine levels of ≥250 ng/mL (data not shown). Participants who reported using ST more hours per day, as well as those who reported more recent use, also had higher adjusted mean serum cotinine levels ($P < .001$). Similar statistically significant results were found for adjusted mean serum nicotine levels (data not shown). Participants who had used ST for more years had higher adjusted mean serum caffeine levels than those who had used ST for a shorter period ($P = .03$, data not shown).

Cotinine and Nicotine Levels and Cardiovascular Risk Factors

There was no difference in adjusted systolic and diastolic blood pressure, pulse rate, white blood cell count, and total or HDL cholesterol levels between participants who used snuff exclusively and those who used chewing tobacco exclusively (Table 4). We examined the association between the above measures and serum cotinine and serum nicotine levels, adjusting for age, race, alcohol use, and serum caffeine (data not shown). There was no association between serum cotinine levels and any of these measures. Interestingly, we failed to confirm our previous finding of a weak inverse association between serum cotinine levels and serum HDL cholesterol levels.[16] However, higher mean serum nicotine levels were associated with higher diastolic blood pressure levels ($P = .02$), and there was a trend toward higher pulse rates ($P = .09$), total cholesterol levels ($P = .10$), and white blood cell counts ($P = .15$) with higher mean serum nicotine levels.

Discussion

This group of professional baseball players is the largest population of ST users in which nicotine and associated cardiovascular risk factors have been examined. The large sample size and the high prevalence of ST use provided ample power to detect relatively minor effects of ST use on the cardiovascular risk factors studied. Despite this, we did not find differences in systolic and diastolic blood pressure, total and HDL cholesterol, and white blood cell count between ST users and nonusers. These findings are similar to those that we reported after the first year of the study[16] and contrast with the results of experimental studies of ST users in which ST use throughout the day produced the same cardiovascular effects as cigarette smoking.[13] Additionally, we analyzed the effect of ST use on serum nicotine and cotinine levels and their association with cardiovascular risk factors.

Cotinine is the major metabolite of nicotine and has a much longer half-life than nicotine.[12] For these reasons cotinine is widely used as a biochemical marker of average daily intake of nicotine. Determination of serum cotinine, however, is a relatively insensitive way to detect exactly when tobacco was last used. The mean serum cotinine level was 144 ng/mL for snuff users and 82 ng/mL for chewers. The average cotinine levels for snuff users were similar to those previously reported in a group of college athletes, but were considerably lower than those measured in a research ward study of ST use and cigarette smoking.[3,13] These cotinine levels are also lower than the average level of 300 ng/mL found in cigarette smokers.[12] Since a cotinine level of 100 ng/mL corresponds to a nicotine intake of about 12 mg,[12] we estimated that daily intake of nicotine was 17.0 mg for snuff users and 9.9 mg for chewing tobacco users. The low

Note. Same abbreviations and units as in Table 2.
[a]Adjusted for age, race, alcohol use, serum caffeine level, hours of smokeless tobacco use per day, time since last ST use and years of ST use.
[b]Subjects included in this table are exclusive users of either snuff or chewing tobacco.

cotinine levels in our subjects were consistent with relatively light use of ST, as reflected by an average of 1.1 hours of snuff use per day and 0.7 hours of chewing tobacco use per day. As expected, serum cotinine levels tended to be higher with greater duration of ST use and greater number of hours of ST use per day, and was lower with greater number of hours since the last dose of ST. Overall, the serum cotinine data indicate that baseball players are relatively light users of ST compared with other populations. Our data also indicate that ST use in baseball players is seasonal; about 50% of the baseball players in our study who reported current-week ST use indicated that they use ST primarily during the baseball season and rarely use it during the off season. The pattern of ST use and low levels of nicotine intake suggests that baseball players may be less dependent on nicotine than are other tobacco users.

Our finding that cotinine levels were lower with chewing tobacco use than with snuff use was surprising in light of the observation that nicotine intake for a single chew is substantially greater than that from a single use of snuff, and daily nicotine levels with ad lib use of both in an experimental study have been found to be similar.[4,13] Our results suggest that chewers use ST in a manner that does not extract as much nicotine from ST as snuff users. The relationship between hours of use per day and serum cotinine was not highly correlated, suggesting that nicotine intake may be more efficient with shorter periods of daily use than with longer periods of use. This type of dose response could be observed if ST is held in the mouth for long periods of time, since the most rapid absorption of nicotine through ST occurs in the first 15 to 20 minutes.[4]

We found an association between higher serum nicotine levels and increased diastolic blood pressure and trends between higher plasma nicotine levels and increased heart rate and white blood cell count. Serum nicotine reflects the recency of tobacco use, and changes in blood pressure, pulse rate, and white blood cell count might reflect a direct pharmacologic response.[12] Our diastolic blood pressure finding is consistent with findings from other studies showing that ST use acutely increases blood pressure.[20,21]

The smokeless tobacco users in this study drank more alcohol than did nonusers. This finding is similar to those of other studies of ST use, in both adolescents and adults.[22] We also found that plasma caffeine levels were higher in ST users than nonusers, perhaps reflecting a tendency toward more psychoactive drug use in ST users. Other studies have found that cigarette smokers drink more caffeine-containing beverages than do nonsmokers.[23] Thus, future studies of the cardiovascular effects of ST should control for the potentially confounding effects of caffeine and alcohol.

Although our findings did not show major adverse effects of ST use on cardiovascular risk factors, we cannot exclude the possibility that daily ST use for many years may have an adverse effect on the cardiovascular system. Previous reports have described long-term harmful effects of ST use, including a strong association with oral cancer.[24–26] Our participants differed from those in other studies of ST use in that their ST use was generally seasonal and of short duration (less than 10 years). Our participants were also professional athletes who exercised regularly and who were generally physically fit, factors that might minimize the harmful effects of ST on the cardiovascular system. Similar large studies should be done in older populations of more sedentary in-

dividuals to detect the impact of ST use in individuals more prone to cardiac disease. □

Morbidity among Pediatric Motor Vehicle Crash Victims: The Effectiveness of Seat Belts

ABSTRACT

It is well established that seat belts reduce mortality and morbidity among children. Data are presented for 413 children injured severely enough in motor vehicle crashes to require hospitalization. Of the unrestrained children, 4.5% died, compared with 2.4% of the belted children. Unrestrained children had a higher proportion of injuries in four of five anatomical regions, were more severely injured, stayed longer in the hospital, and were 15% more likely than belted children to be discharged with impairments. (*Am J Public Health.* 1992;82:422–425)

J. Scott Osberg, MA, and Carla Di Scala, PhD

Introduction

Despite efforts to reduce motor vehicle fatalities and injuries via restraint laws, speed limits, and alcohol awareness programs, these injuries remain one of the most frequent causes of death and disability for children.[1] Although there is little doubt that use of seat belts reduces fatalities,[2,3] serious injuries, and concomitant medical costs,[3,4–11] belts can cause certain injuries, particularly in the 4-to-9 age group, in which children are too big for child safety seats and too small for adult belts.[12] Injuries associated with belt use include chest and abdominal injuries,[13–16] cervical spine fractures,[17] cardiac contusion,[18] and rupture of the stomach.[19]

This paper focuses on the effectiveness of seat belts in reducing injuries among survivors aged 4 to 14 who are admitted to hospitals. The study contrasts outcomes for belted versus unrestrained children among the middle range of children involved in motor vehicle crashes—those requiring hospitalization.

Methods

Data are from the National Pediatric Trauma Registry, Phase II.[20] The Phase II registry population contained 7156 children injured from all causes from October 1988 to March 1990, 1150 of whom were injured in motor vehicle crashes. Children in crashes not occurring on the road, those riding in pickup trucks or buses, children younger than 4 or older than 14 years, and 43 cases in which restraint use was unknown were excluded. Uninjured children, those receiving only emergency room services, and children dead at the scene were excluded. Of the remaining 413 children, 290 were unrestrained and 123 were belted. This hospital-based sample was expected to reduce differences between the two groups, as children on either end of the motor vehicle crash spectrum (those unscathed and those who died at the scene) were excluded. No information was available on vehicular speed(s) or side of impact, which may have influenced outcome.

Outcome variables include mortality, severity of injury, body regions affected, impairments, and utilization of health services. Three injury severity measures are considered: the Abbreviated Injury Scale (AIS),[21] the Injury Severity Score (ISS),[22] and the Glasgow Coma Scale.[23] Injured children were classified according to the most severely involved ISS body region, identified by the maximum AIS score.[24] The ranking system of MacKenzie et al.[24] is used to assign the principal injury when there are ties for the most severely injured AIS body region. Impairments at discharge were assessed in nine areas of daily functioning: vision, hearing, speech, self-feeding, bathing, dressing, walking, cognition, and behavior.

Results

Of the 123 belted children, 40.5% were male; 50.2% of the 290 unrestrained

children were male. The average age of the children in both the belted and unrestrained groups was 8.5 years. The two groups were similar in proportions of front- and back-seat passengers and crash types (Table 1). However, unrestrained children tended to be more severely injured, to have higher mortality rates (Table 2), and to use more services (Table 3). As expected, unrestrained children were more likely to have head/neck injuries, as well as injuries to the face, thorax, and extremities (Figure 1). As found in earlier studies,[14–16] belted children were somewhat more likely to have injuries to the abdomen. Head/neck and thoracic injuries posed the greatest survival threat to both groups (Figure 2).

The abdominal region deserves special attention, as it is the one area where belted children were more severely injured. Whereas 22.3% of the unrestrained children had moderate to severe abdominal AIS scores, 31.7% of belted children had AIS scores in this range (Figure 2). Table 4 displays the constellation of injured body regions for the subset of children with primary abdominal injuries. Belted children had either abdominal injuries alone (57.1%) or abdominal and external injuries (42.9%), whereas 33.3% of the unrestrained children had injuries to a variety of body regions.

Unrestrained children were more likely to have head/neck, extremity, or thorax injury than were belted children, who were more likely to have abdominal or "other" as their primary injury (Figure 3). As determined by the ISS of the primary injury, unrestrained children, particularly those classified with primary injuries to the head/neck or abdomen, were more seriously injured. Finally, 70.6% of the belted children, compared with 54.8% of the unrestrained children, were discharged with no impairments (Figure 4).

Discussion

Analysis of this multi-institutional sample demonstrates that seat belts do more than "merely" reduce the incidence of injury and concomitant mortality. Despite the homogenizing effect of this hospital-based sample, the results suggest that belts reduce morbidity, with everything this reduction implies in terms of quality of life and reduced health care costs. Belted survivors were less severely injured, were hospitalized for shorter periods, were less likely to be discharged with residual impairments, and consequently were less likely to need health services following discharge. Thus, not only do seat belts reduce health costs by preventing injuries,[4–6,10] but even in the subset of children who require hospitalization, the use of seat belts results in the consumption of fewer resources.

Belted children were found to have more abdominal injuries of greater severity than did unrestrained children. However, unrestrained children with primary abdominal injuries also had injuries to other body regions, which left them more severely involved overall. Although belted children had more severe abdominal injuries, the low risk of sustaining serious belt-related abdominal injuries is overshadowed by the greater risk of sustaining other serious injuries if seat belts are not used.[14] Although clinicians should be alert to signs of "seat belt syndrome" among belted children,[14–16,25] we agree with Cameron[26] that seat belt syndrome should be de-emphasized so parents don't misinterpret the findings and allow children to go unbelted.

The optimal protection system has not yet been designed; continued improvements are needed.[14,26–28] Reid et al.[29] support Agran et al.[30] in recommending the "use of specially designed passenger restraints in children up to the age of 10 years."[29] However, Reid et al. also report

that seat belts are associated with pediatric chance fractures: "While seatbelts may in fact save lives and reduce mortality, their use may inadvertently lead to an increased morbidity of the survivors of high-impact motor vehicle accidents in the pediatric population."[29] This speculation is not supported by the data in our sample, where there appears to be no increased morbidity among belted survivors. In fact, the reductions in the incidence of injury and in mortality rates for belted children noted elsewhere[3,4–11] were matched in our sample by reductions in short- and long-term morbidity. Seat belts are an effective means of prevention, and even current adult designs are capable of producing important reductions in morbidity in pediatric populations. In short, any restraint is better than no restraint.[27] □

Pediatric Gonococcal Infection, Florida, 1984 to 1988

Jean-Claude A. Desenclos, MD, David Garrity, and Jack Wroten

ABSTRACT

We reviewed Florida pediatric gonococcal (GC) infection surveillance data collected between 1984 and 1988. The incidence rate was 11 per 100 000 per year for the age group 1 month through 9 years. Incidence rates were higher for females, other-than-Whites, and residents of rural counties than for males, Whites, and residents of urban counties. The ratio of pediatric GC cases in children younger than 10 years per 1000 adult male GC cases, a substitute measure for the proportion of males that may have perpetrated child sexual abuse, was 3.3 for Whites and 4.9 for other-than-Whites, and was higher for residents of nonmetropolitan counties (9.7) than for residents of metropolitan counties (4.2). These data highlight the importance of GC infection in children and suggest that routine surveillance of pediatric GC infection may be a useful tool for monitoring the occurrence of child sexual abuse. (*Am J Public Health*. 1992;82:426–428)

Introduction

Sexual abuse of children is receiving increasing attention; there are an estimated 100 000 to 500 000 victims per year in the United States.[1] Although misidentification of organisms such as *Neisseria gonorrhoeae* has been reported in children,[2] the isolation of a sexually transmissible pathogen from a child, when infection in utero or during delivery can be excluded, is presumed to be evidence of sexual abuse.[3] Gonorrhea is the most frequently reported sexually transmitted disease (STD) in children who have been sexually abused.[4] To estimate the public health importance of pediatric gonococcal (GC) infection in Florida and to describe its epidemiology, we reviewed surveillance data collected by the Florida Department of Health and Rehabilitative Services Sexually Transmitted Diseases program.

Methods

Public and private health care providers are required by law to report laboratory-confirmed episodes of GC infection to the Florida STD Program. The number of cases reported is computed each year by race (White and other-than-White) and sex, by age (0 to 9 years and by 5-year age groups over 9 years). For cases that occur among children younger than 13 years, a confidential morbidity card is completed by STD investigators with name, address, age, sex, race, date of diagnosis, site of GC infection and treatment, and forwarded to the STD Program. We reviewed morbidity cards that reported episodes of GC infection diagnosed between January 1, 1984, and December 31, 1988, in children aged 1 month through 12 years. A cluster of childhood GC infection was defined as two or more cases reported in children living at the same address and diagnosed within a 3-month interval. A recurrence was defined as two treated episodes of GC infection in a child separated by a time interval of at least 1 month.

Incidence rates of GC infection episodes per 100 000 children per year were calculated for the age group 1 month through 9 years by sex, race, and county of residence grouped as nonmetropolitan (no city with more than 50 000 residents) and metropolitan (at least one city with more than 50 000 residents). The 1986 mid-year Florida population under 10 years was used for rate calculation. We calculated the ratio of cases in children aged 1 month through 9 years to GC cases in males older than 14 years reported for the same time interval as an indicator of the proportion of male adults with GC infection who may have perpetrated child sexual abuse. Rates and ratios were standardized for race by the direct method.

Results

Eight hundred twenty-two cases of GC infection in children aged 1 month through 9 years were reported from 1984 to 1988. The review of available morbidity cards identified 854 episodes in 849 children aged 1 month through 12 years; 87% of these GC infection episodes were genital, 79% occurred in females, and 84% occurred in other-than-Whites (Table 1). Numbers of cases tended to be similar by age for males but not for females (Figure 1). Twenty clusters of pediatric GC infection were identified (16 clusters of two cases and 4 clusters of three cases). Five children had recurrent infections.

The overall incidence rate for the age group 1 month through 9 years was 11 per 100 000 per year. Incidence rates were higher for girls (18.2) than for boys (4.1) and for other-than-Whites (38.4) than for Whites (2.5). The race-adjusted incidence rate was higher for nonmetropolitan counties (15.6) than for metropolitan counties

At the time of this study, Jean-Claude A. Desenclos was with the Division of Field Services, Centers for Disease Control, and was assigned to the Florida Department of Health and Rehabilitative Services. [b]Includes disseminated gonococcal infection (n = 4) and pelvic inflammatory disease (n = 13).

(8.1). The ratio of cases in the age group 1 month through 9 years to cases in males older than 14 years was 1.5 times greater for other-than-Whites (4.9:1000) than for Whites (3.3:1000), and was more than two times higher in nonmetropolitan counties (9.7:1000) than in metropolitan counties (4.2:1000) (Table 2).

Discussion

The Florida STD surveillance system identified a substantial number of pediatric GC infections that were very likely to have been transmitted through sexual abuse; it also detected clusters and recurrences. Previous reports have indicated that perhaps less than 6% of child molestations are ever reported.[1] Although nonsexual transmission may occur,[5] STDs in children are most often the result of sexual abuse.[3] Thus pediatric GC surveillance data may provide specific indicators to assess the importance of child sexual abuse in a community.[6–9]

Our data provide a description of the problem statewide, and may differ by demographic characteristics from some hospital based case-series data.[4,8,10–12] However, the clinical presentation is consistent with previous reports of pediatric GC infection case series,[4,7,8,10–13] and the age and sex distribution are also similar to that reported in two hospital-based studies of sexually abused children.[14,15]

However, the Florida pediatric GC infection episodes were not representative of the occurrence of child sexual abuse by race. Because the prevalence of GC infection is higher in Florida for other-than-

Race	County of residence		
	Metropolitan	Nonmetropolitan	All counties
White	2.7	9.4	3.3
	(107:39 478)	(38:4050)	(145:43 528)
Other than Whites	4.6	9.8	4.9
	(586:127 231)	(94:9613)	(680:136 844)
Total[a]	4.2	9.7	4.6
	(693:166 709)	(132:13 663)	(825:180 372)

Note. Actual ratios are shown in parentheses.
[a] Standardized for race by the direct method.

Whites than for Whites,[16] the difference of pediatric gonorrhea incidence by race may not reflect a difference in the occurrence of child molestation. The child-to-adult case ratio, an attempt to adjust for the prevalence of GC infection in adult males (an indicator of the number of male adults with GC infection who may have perpetrated child sexual abuse), were mostly similar by race. Because it has not been used and validated previously, this ratio must be interpreted with caution; it assumes that all pediatric cases are sexually transmitted and that each perpetrator with gonorrhea infects only one child. However, the ratio was in the order of magnitude of the rates of confirmed child sexual abuse (of children younger than 15 years) investigated in Florida during fiscal year 1989 (Whites, 6121 victims, rate = 3.4 per 1000; non-Whites, 2043 victims, rate = 3.7 per 1000 [Florida Department of Health and Rehabilitative Services, Child, Youth and Family Services, unpublished data, 1989]). A bias toward a higher rate for other-than-Whites is possible, because other-than-Whites seek health care at public clinics more often than do whites[16]; therefore, their reportable diseases may be more likely than those of Whites to actually be reported. Pediatric GC rates were higher for nonmetropolitan areas than for metropolitan areas, a finding not previously reported.

Guidelines recommend that the identity of an STD agent isolated from a victim of sexual child abuse be confirmed by recognized laboratory methods.[2,3] Because they were not validated, the data presented in this paper need to be considered carefully. However, pediatric STD reporting systems may represent an alternative method of surveillance for child sexual abuse and warrant further evaluation. □

Evaluation of an Intervention to Reduce Playground Hazards in Atlanta Child-Care Centers

ABSTRACT

In 1988, we identified playground hazards at 58 child-care centers (CCCs) and intervened by showing the director the hazards and distributing safety information. In 1990, we evaluated the 58 intervention CCCs as well as 71 randomly selected control CCCs. Intervention centers had 9.4 hazards per playground; control centers had 8.0. We conclude that the intervention was ineffective. (*Am J Public Health.* 1992;82:429–431)

Jeffrey J. Sacks, MD, MPH, Mary D. Brantley, MPH, Patricia Holmgreen, MS, and Roger W. Rochat, MD

Introduction

A 1988 study of child-care centers (CCCs) found that the likelihood of a playground-related, medically attended injury increased as the number of identified playground hazards increased.[1] Part of that study involved an intervention in which we showed the director each identified hazard and distributed playground safety information. In 1990, we revisited these centers to see if the hazards had been corrected.

Methods

Methods for the sample selection and hazard survey have been described.[1,2] Briefly, 66 of 71 randomly selected CCCs enrolled in an injury study[2] underwent evaluation for commonly recognized playground hazards[3–6] (see also Table 1) between July and October 1988 (the baseline survey).[1]

The intervention consisted of pointing out and explaining each hazard to the CCC director, and distributing results of the injury study[2] and handbooks on playground safety.[7,8]

We had two questions: (1) would the intervention result in less hazardous playgrounds (intervention vs control study)? and (2) would specific hazards previously pointed out to CCC directors in 1988 be eliminated (persistence study)?

In April and May 1990, 16 CCC licensing inspectors with the Georgia Department of Human Resources Office of Regulatory Services (ORS) were trained in playground evaluation. Between May and June 1990, two-person teams of these inspectors evaluated all baseline survey CCCs and 71 randomly selected control CCCs (the follow-up survey). Inspectors were not told which CCCs were controls. Inspectors drew a map, inventoried equipment, measured equipment heights and undersurface thickness, listed hazards, noted the director's name and length of incumbency, and formed an overall impression of playground safety (very hazardous, hazardous, average, safe, very safe).

We also reviewed ORS annual licensing evaluations for 1988–1989 for all follow-up survey CCCs.

Intervention vs Control Study

We compared mean and median number of hazards per center and playground, and the inspector's impression of safety. Intervention CCCs were categorized by change in directorship after the intervention in 1988; control CCCs, by a change after September 1, 1988.

Persistence Study

Intervention center playgrounds and equipment were linked to the baseline survey by location and equipment height; those that could not be linked were excluded. Hazards were considered persistent if baseline and follow-up coding categories matched exactly.

Results

Intervention vs Control Study

Of 66 baseline survey CCCs, 58 were open in 1990. These CCCs had 123 playgrounds with 1171 pieces of equipment; the 71 control CCCs had 135 playgrounds and 1021 pieces of equipment. Climbing equipment was the most common piece of equipment. Of 238 climbers at least 4 feet tall, 125 (52.5%) were sited over nonresilient surfaces (earth or grass, concrete);

Other	60 (1.0)	71 (1.0)	131
Total	463 (8.0)[c]	477 (6.7)[c]	940
Equipment-related			
Exposed concrete anchoring	71 (1.2)	67 (0.9)	138
Inadequate clearance	58 (1.0)	56 (0.8)	114
Rocks in fall zone	54 (0.9)	49 (0.7)	103
Exposed nail	47 (0.8)	43 (0.6)	90
Splintered wood	50 (0.9)	39 (0.6)	89
Open "S" hooks on swings	44 (0.8)	44 (0.6)	88
Rusting	27 (0.5)	28 (0.4)	55
Exposed root in fall zone	26 (0.5)	25 (0.4)	51
Sharp objects	29 (0.5)	25 (0.4)	54
Tip-over hazard[d]	25 (0.4)	24 (0.3)	49
Other	179 (3.1)	189 (2.7)	368
Total	610 (10.5)[e]	589 (8.3)[e]	1199

[a]Not including inadequate undersurfacing in fall zones.
[b]Data shown for those hazards recorded 40 or more times in the 129 centers.
[c]Standard deviation (SD) = 5.4 for intervention and 5.5 for control CCCs.
[d]Climbing equipment accounted for 10 (6 intervention, 4 control) of these hazards.
[e]SD = 9.2 for intervention and 8.7 for control CCCs.

only 17 (7.1%) had 3 or more inches of loose-fill undersurfacing.

Intervention and control CCCs had similar licensed capacities. Their playgrounds were designed for similarly aged children. The mean incumbency for intervention center directors was 8.4 years; for control center directors, 8.6 years. No control center directors had received the intervention.

The inspectors identified 2139 hazards (mean = 16.6, median = 13, range = 1–69) in the 129 CCCs. The median number of hazards per playground was 7.0; only 14 of 258 playgrounds had no hazards.

Intervention CCCs had 1.3 more hazards unrelated to equipment than control CCCs had and a mean of 2.2 more equipment-related hazards (Table 1). Intervention CCCs also had higher hazard scores (Table 2). The 32 centers with no change in directorship had higher hazard scores than the 26 centers with a change. Control CCCs with no change in directorship also had more hazards per playground than those with a change (mean = 9.3, median = 8 vs mean = 7.3, median = 6, respectively). As licensed capacity increased, playground hazard scores decreased (Table 2).

Of 118 intervention playgrounds, 47 (39.8%) were deemed "very safe" or "safe," 42 (35.6%) were "average," and 29 (24.6%) were "hazardous" or "very hazardous"; the corresponding figures for 127 control playgrounds were 43 (33.9%), 44 (34.6%), and 40 (31.5%). These differences were not statistically significant.[9] For intervention CCCs with no change in directorship, 28.8% of 59 playgrounds were rated "hazardous" or "very hazardous" compared with 20.3% for CCCs with a change. For control CCCs with no change in directorship, 41.5% of playgrounds were rated "hazardous" or "very hazardous" compared with 23.5% for CCCs with a change.

Licensing evaluation reviews revealed that, between 1988 and 1989, playground hazards increased from 85 to 104 for 53 intervention CCCs and decreased from 81 to 73 for 57 control CCCs. The 29 intervention CCCs with no change in directorship went from 49 hazards in 1988 to 63 in 1989. Of the 177 hazards noted in 1989, 41 (23.2%) had been cited in 1988.

Persistence Study

We linked 111 (90.2%) of 123 intervention playgrounds and 589 (51.7%) of 1140 pieces of equipment to baseline. At follow-up, we identified 150 (36.0%) of 417 hazards noted at baseline. For CCCs with a change in directorship, 48 of 153 hazards persisted (31.4%) compared with 102 of 264 hazards (38.6%) for CCCs with no change.

Discussion

At CCCs, most injuries requiring medical attention occur on playgrounds.[2,10–12] To reduce such injuries, we intervened, showing each director the specific hazards on the playground, explaining why they were problematic, and distributing educational materials.

Despite this intervention, quantitative scores indicate that intervention CCC playgrounds were not less hazardous than control playgrounds. Similar results were obtained from independent data—the annual licensing evaluations.

If the intervention had been effective, we would have expected CCCs with the same "intervention-exposed" director to have lower hazard ratings than CCCs with new, "unexposed" directors. The opposite occurred. Hazard persistence rates and subjective safety ratings were also worse in CCCs with intervention-exposed directors. This does not imply that the intervention had a negative effect. Rather, lower hazard ratings in control CCCs with changes in directorship suggest that leadership changes may be important in reducing hazards.

Almost 2 years after the intervention, 36% of the hazards found at baseline persisted. We cannot assume that the remaining 64% of the hazards were abated. The 1990 survey had 16 evaluators; the 1988 survey had only 3. What one team labeled an "exposed rock," another team may have called a "tripping hazard." Because we counted only exact matches, differences in nomenclature probably led to an undercount of true persistence.

Regulations do not ensure "hazard-free" environments. Although they are not defined, hazardous conditions are prohibited on center grounds. Nevertheless,

inspectors identified 2139 hazards in 129 CCCs. Georgia codes also mandate resilient surfaces beneath climbers without defining resilient. For climbers at least 4 feet tall, earth or grass is not considered a suitable undersurface,[13-14] and loose-fill undersurfaces (sand, wood chips, etc.) require 6 or more inches in depth.[3,13-16] Yet few CCCs followed these recommendations. As a result of this study, the State of Georgia has revised CCC regulations (effective March 1, 1991) to provide specific definitions of selected playground hazards.

The lack of better hazard scores in intervention CCCs, the better hazard ratings for intervention CCCs with intervention-*unexposed* directors, and the higher hazard persistence rates in CCCs with intervention-exposed directors support our conclusion that pointing out and explaining playground hazards to CCC directors, coupled with distributing educational materials, does not reduce hazards. Alternative approaches that need evaluation include rewriting regulations, training agency inspectors better, enforcing regulations more rigorously, educating CCC directors more extensively, and increasing parental awareness—for example, by posting inspection results in a conspicuous place in the CCC. □

TABLE 2—Hazard Scores of Intervention and Control Child-Care Centers (CCCs), by Change in Directorship, Atlanta, Ga, 1990

	Mean (Median) Scores				
	Intervention CCCs				
Number of Hazards	Same[a]	New[b]	Total	Control CCCs	All CCCs
Per CCC[c]	19.3 (15.5)	17.6 (13)	18.5 (15)	15.0 (11)	16.6 (13)
Per playground, by licensed capacity					
<60[d]	12.2 (12)	10.8 (10.8)	12.0 (11)	9.5 (8)	10.6 (9)
60–89[e]	6.2 (7.3)	8.3 (8)	7.3 (7.3)	9.5 (9)	8.3 (7.7)

Air Quality during the Winter in Québec Day-Care Centers

Serge Daneault, MD, MSc, Monique Beausoleil, BSc, and Karen Messing, PhD

ABSTRACT

Over 90% of 91 day care centers in greater Montréal, Québec exceeded 1000 ppm of CO_2 during January through April 1989. Four variables were independent positive predictors of CO_2 levels: the density of children in the center; presence of electric heating; absence of a ventilation system; and building age. High levels of CO_2 are associated with respiratory tract and other symptoms. Clear standards and inspection policies should be established for day care center air quality. (*Am J Public Health.* 1992;82:432–434)

Introduction

Indoor air pollution in nonindustrial workplaces has recently become a focus of interest.[1–3] Studies of this phenomenon have concentrated on office buildings.[4–8] Recently, Scandinavian researchers[9–11] found inadequate ventilation in schools and day-care centers, especially those built during the 1980s.[9–11] Although small numbers of such centers were studied, these studies alert us to a problem potentially affecting the health of many very young children. In the United States, 18% of children under 6 were enrolled in day-care centers in 1982,[12] and this proportion is increasing.

In order to address this question, air quality was monitored in 91 day-care centers, representing 86% of such centers in the South Shore and eastern regions of Greater Montreal. The study was designed to assess air pollution and other physical conditions in the centers, and, in a second stage, to relate them to the health of the children attending the centers. We present here the assessment of physical conditions.

In this study, the temperature, percentage of relative humidity, and levels of carbon dioxide (CO_2) were chosen because they are (1) easy to measure, (2) reliable indicators of ventilation quality, (3) recommended by regulating agencies as the first step of tight building evaluations, and (4) used by Scandinavian researchers, providing a basis for comparison.[13–15] It should be noted, however, that toxic levels of unmeasured substances may persist in the presence of low levels of these indicators, particularly in the case of multiple-vocation buildings.

Methods

Choice of Day-Care Centers

A list of Montreal eastern region and South Shore day-care centers was derived from the lists of the provincial government registry that licenses such centers. In December 1988, a letter explaining the study was sent to each center, and this was followed by a phone call in January 1989 to request participation. Eighty-six percent participated in the study, almost all of which accept only children under 6.

General Characteristics of Centers

Each day-care center was visited on one afternoon between January 3 and April 15, 1989. Outdoor temperatures during this period ranged from −25°C to 16°C during the day, with a mean of 3°C. A technician noted, on a preformatted data sheet, characteristics of the building, the heating and air conditioning systems, ventilation and room division, and details of occupancy such as number of children per square meter of space and potential sources of air pollution.

Measurement of Indoor Air Characteristics

CO_2 was measured with an extra low range tube (Gastec Corporation) and relative humidity and temperature levels with a sling psychrometer (Bacharach Instruments). Measurements were taken in each of the five rooms most often occupied by children and were repeated four times: before, during, and after the afternoon nap and again before the children left. Because some day-care centers had fewer than five rooms, a total of 1672 measurements were taken. For 205 of these, CO_2 was measured simultaneously with an infrared gas analyzer (PM-2, ADC Company). Although the two measures

differed by an average of 32 ppm, in only four cases was there a difference greater than 300 ppm.

Data Analysis

The Statistical Package for Social Sciences (SPSS) program was used to calculate χ^2 values, and a stepwise multiple regression was constituted to predict carbon dioxide levels.

Results

CO_2 Levels

The CO_2 levels for the 91 day-care centers are shown in Table 1. There is no prescribed limit for day-care centers, but the average level for all 1672 measurements was 1505 ppm, well over the office building standard of 1000 ppm,[13] even considering the imprecision of the Gastech tubes. Only 9 of the 91 centers never exceeded 1000 ppm, and 13% exceeded 2500 ppm.

Relative Humidity and Temperature Levels

The relative humidity levels are reported in Table 2. The American Society for Heating and Refrigerating and Air Conditioning Engineers[16] recommends that humidity levels not be below 30% during winter. To our knowledge, there are not recommended levels specifically for day-care centers, but Canadian recommended winter levels for residences are 30% to 55%.[17] The levels of relative humidity were in the recommended range in 76 day-care centers (83%). Temperature was in the comfort zone (20°C to 23.6°C)[16] in 92% of the centers.

Predictors of CO_2 Levels

In order to focus efforts to diminish pollution, CO_2 levels were related to various building and occupancy characteristics. The results of the stepwise multiple regression are shown in Table 3. Four variables were significant and independent predictors of CO_2 levels. The main predictor was the density of children in the center when the measurements were made. Each child present per cubic meter increased the level of CO_2 by nearly 70 ppm. The use of an electric heating system (in 63% of the centers) increased the mean CO_2 level by 250 ppm. The presence of a ventilation system (in 32% of centers) reduced CO_2 levels by a mean of 562 ppm. Each year of building age decreased the level of CO_2 by 12 ppm. Thus, a building built in 1949 would be expected to have CO_2 levels 480 ppm lower than one built in 1989.

TABLE 1—Carbon Dioxide (CO_2) Levels in 91 Quebec Day-care Centers.

CO_2 level, [a]	Mean[b]		Minimum		Maximum	
	n	%	n	%	n	%

[b]Four measurements in each of five rooms per center.

TABLE 3—Prediction of Mean Carbon Dioxide Levels by Building Characteristics of Day-care Centers

	Label	Step of Entry	β (SD)	R^2 Change
Density of children (per 100m^3)	Continuous	1	67.50 (19.91)	.1275
Heating system	1:Electric 0:Other	2	250.29 (181.12)	.0916
Artificial ventilation	0:No 1:Yes	3	−562.30 (179.14)	.0659
Age of building	Continuous	4	−12.07 (5.23)	.0512
Constant			1383.51	
Total R^2 = 0.34				

Note. The following additional variables were tested and not retained in the regression: building intended as day-care center (yes/no); renovation (yes/no); heating system controlled centrally (yes/no); hours of operation (coninuous); outdoor temperature, relative humidity, and wind speed (continuous).

Discussion

Air Quality in Day-Care Centers

Air quality was not good in the day-care centers. In a study in which Montreal day-care centers were very well represented, over 90% of centers exceeded 1000 ppm CO_2 at some time during the study, and 13% exceeded 2500 ppm. One sixth of the centers had humidity levels outside the accepted range. These results were obtained during afternoons of winter months in a northern region. That this may be a common problem is shown by the comparable results of Scandinavian researchers, who found levels over 4000 ppm in two day-care centers.[9]

Levels of CO_2 were related, as expected, to level of occupation, since CO_2 is produced mainly by human respiration. CO_2 level was also related to ventilation, either by a ventilating system or by natural air exchange in the case of older buildings. Since the variables had independent effects, we believe that the type of heating system and building age are not just sur-

TABLE 4—Energy Source for Heating as a Function of Building Age among 89 Day-care Centers in Quebec[a]

rogate measures for the quality of building insulation. Electric heating is usually installed in new or recently renovated buildings (Table 4).

The level of CO_2 is important in itself, since it has been related to various symptoms, such as nasal discharge, eye irritation, throat dryness, headache, dry skin, and lethargy.[3,6,14] In addition, the level of CO_2 is an indicator of the quality of ventilation in general, and may thus serve as a marker for other pollutants, not verified in the present study, such as carbon monoxide and formaldehyde.[13,17]

Adequacy of Standards for Day-Care Centers

If the CO_2 levels and some of the humidity levels described in this study had been found in office buildings, immediate action would have been recommended according to the limits suggested by the American Society for Heating and Refrigerating and Air Conditioning Engineers.[13] Day-care center exposures not only involve workers, but also children. Also, the limit of 1000 ppm for CO_2 supposes an exposure time of 8 hours, while children and personnel may occupy day-care centers for as long as 12 hours per day.

Air quality standards appropriate to the use characteristics of day-care centers have not yet been developed. Buildings used for day care are only required to respect the current norms for buildings and occupancy generally in use in North America, in terms of numbers of children per unit area and height of ceilings. It may be that these standards are not adequate to protect the health of occupants of day-care centers. One study, for example, showed that children attending day-care centers suffered more illnesses than children at home.[18] Infectious diseases in crowded day-care centers may result from a synergistic effect of increased contact and poor ventilation, resulting in inadequate removal of microorganisms. If there is a link between these and other health effects and ventilation characteristics, criteria for day-care ventilation and building use should be adjusted. □

Infant Mortality, Per Capita Income, and Adult Illiteracy: An Ecological Approach

R. Tresserras, J. Canela, J. Alvarez, J. Sentis, and L. Salleras

ABSTRACT

The ecological association of infant mortality rate (IM) with per capita income (PI) and prevalence of adult illiteracy (AI) has been studied using countries as the unit of analysis. A negative association between IM and PI in 1960 and 1982 has been observed (sample correlation coefficient [r] = –.625 and r = –.729, respectively; $P < .05$). A correlation between IM and AI has been found for both men and women ($r = .827$ and $r = .855$, respectively; $P < .05$). The ecological relative risks were 7.43 for men and 5.82 for women (95% confidence intervals: 5.16–10.71 and 4.36–7.75, respectively).

The association of IM and PI shows a slight but not significant improvement between 1960 and 1982. AI can be considered a good predictor of IM in countries. (*Am J Public Health.* 1992;82:435–438)

Introduction

Infant mortality (IM) has often been used as an indicator of community health level,[1] and it has been found to be associated with some socioeconomic and cultural variables.[2–10] Moreover, a significant correlation between IM, per capita income (PI); and adult literacy in 92 countries has recently been reported.[11]

The objectives of this paper are (1) to study the possible changes in the relationship between IM and PI, comparing data from 1960 and 1982; and (2) to assess the prevalence of adult illiteracy (AI) as an indicator of the ecological risk level of IM in a community.

Material and Methods

Data on IM[12] are from 1960 and 1982, data on PI are from 1962 and 1982, and data on AI are from 1980 and are calculated in real terms according to 1980 US dollar market prices.[13] This adjustment was made to avoid the effects of inflation and exchange changes.

For IM and AI, data were obtained from 103 countries; for PI, data were obtained from 82 countries for 1962 and from 95 countries for 1982. For each variable, all available data were included in each case. The 82 countries with available data on PI in 1962 were also included in the 95 countries with available data on PI in 1982, and all of these were included in the 103 analyzed countries.

To study how the association of IM and PI differed between 1960 and 1982, the difference in regression coefficients for both years was analyzed.[14] Correlation between observed and expected IM rates for 1982 was also studied, applying the 1960 regression equation.

To estimate the ecological relative risk (RR), the weighted logistic regression method proposed by Silcocks and Murphy[15] was used. The weight of each country was made according to the number of births, estimated from the total population and its crude birth rate. The weight was used to adjust for the relative influence of each country in the model, thereby preventing small or large countries from dominating the analysis.

Normal distribution of all variables was checked using the Kolmogorov-Smirnov test. Normalization of PI for the studied years was obtained by applying natural logarithms to original data.[16]

Results

Table 1 shows the main parameters for the studied variables. The correlation between IM and PI was statistically significant for 1960 and 1982 (sample correlation coefficient [r] = –.625 and r = –.729, respectively, $P < .05$) (Figures 1a and 1b). The regression equations were

$$1960: \text{IM} = 337.144 - 32.460 \cdot \ln \text{PI}$$

$$(R^2 = .3906) \quad (n = 82),$$

$$1982: \text{IM} = 275.543 - 28.234 \cdot \ln \text{PI}$$

$$(R^2 = .5315) \quad (n = 95).$$

Although PI may explain a greater IM variability for 1982 than for 1960, no differences in regression coefficients were found ($t = .83$). The correlation between observed and expected IM rates for 1982 was $r = .73$ ($P < .05$).

AI prevalence was greater in women than in men (43.3% vs 25.5%; $z = 3.85$; $P < .05$). The correlation between IM and AI was positive and statistically significant for both men and women ($r = .827$ and

TABLE 1—Infant Mortality (IM) Rates (1960 and 1982), Per Capita Incomes (PI) (1962 and 1982), and Prevalences of Adult Illiteracy (AI) (in Men and Women, 1980).

Variable	Mean/Median/ Weighted Prevalence	Minimum value	Maximum value	n
IM 1960 10^3	116[a]	26	230	103
IM 1982 10^3	84[a]	7	200	103
PI 1962 ($)	665[b]	117	21 131	82
PI 1982 ($)	1074[b]	74	21 314	95
AI men (%) (1980)	25.5[c]	1	86	103
AI women (%) (1980)	43.3[c]	1	98	103

Note.—n = number of countries with available data.
[a]Mean.
[b]Median.
[c]Weighted prevalence based on 1980 population.

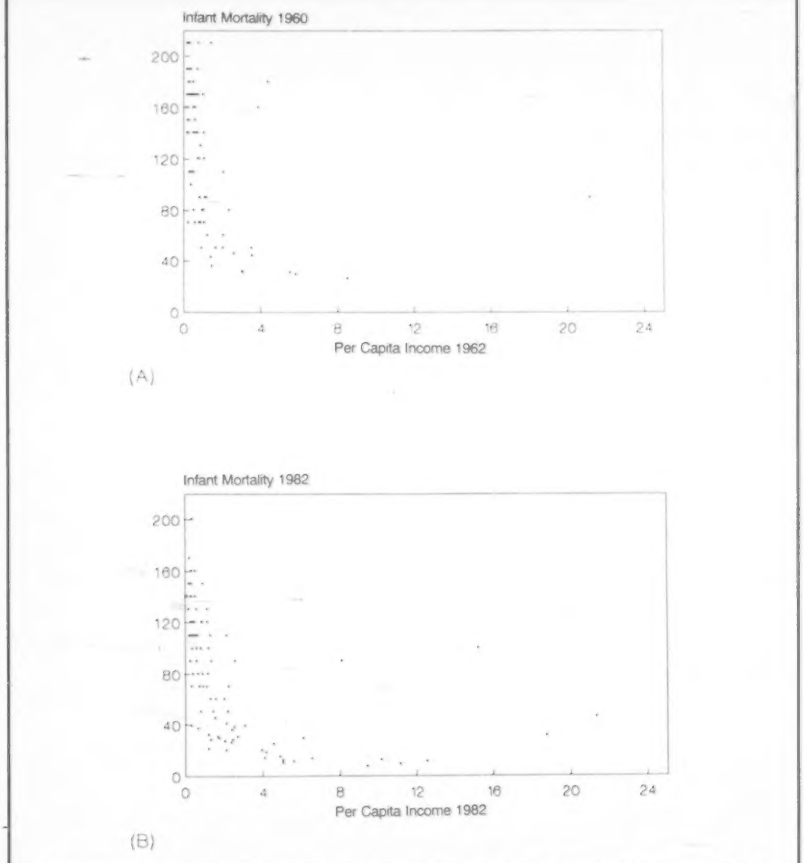

FIGURE 1—Correlation between infant mortality rate and per capita income (US dollars) in 1960 (1a) and 1982 (1b). PI in arithmetic scale.[12,13]

$r = .855$, respectively; $P < .05$) (Figures 2a and 2b). The regression equations were

$$\text{Men: IM} = 27.835 + 1.649 \cdot \text{AI} \quad (R^2 = .684),$$

$$\text{Women: IM} = 18.376 + 1.356 \cdot \text{AI} \quad (R^2 = .731).$$

The ecological relative risk was 7.43 for men and 5.82 for women (95% confidence intervals: 5.16–10.71 and 4.36–7.75, respectively).

Discussion

Although data could be obtained for only 103 countries, these countries represent approximately 90% of the world's population (4500 million people) (Figure 3).

The results support an association at the ecological level between IM and independent variables, such as PI and AI. Although there was an important reduction in IM rates from 1960 to 1982, IM is still considered high, being $84 \cdot 10^3$ in 1982.

Regarding the association of IM and PI, the observed 1982 IM rate was very similar to the expected rate, and there are no differences between regression coefficients although data show an improvement in absolute terms. This suggests that the association between these variables did not change significantly during the study period. However, a negative exponential association was observed. Figures 1a and 1b (in arithmetic scale) show that there is a vertical branch formed by developing countries and a horizontal one formed by industrialized countries, with the oil-exporting countries between them. It should also be noted that while maximum income increases, minimum income decreases.

A significant difference related to AI was observed between sexes. Although this type of difference is difficult to analyze in this kind of study, sex differences do not seem to explain the higher or lower IM risk in the studied countries. However, at the ecological level, countries with higher prevalence of AI among both men and women also show a significantly higher rate of IM. Furthermore, there is also an association between PI and AI, and the relationship between IM and AI is at least as strong as that existing between IM and PI. In a previous report,[11] we found that both PI and AI were included in a regression stepwise model.

Over the study period, developed countries showed the highest improvement in their IM rates. Only oil-exporting countries showed a similar proportional reduction, but they were still far behind despite their very high PI levels.

In interpreting the results, the possible presence of some biases has to be taken into account. These biases can be due to the countries selected (in this case, available data for all of them came from

the same source) or to the fact that data are estimated by international organizations. Moreover, PI does not reflect the wealth distribution of a country, nor does AI reflect the general cultural level of the different social groups. Finally, to avoid the ecologic fallacy,[17,18] these results cannot be regarded at an individual level.

If the above-mentioned aspects are considered, it can be said that PI and AI are variables that have to be taken into account in studying IM rates in countries. Relevant changes have not been found in the association of IM with PI between 1960 and 1982. AI can be considered a good predictor of IM in countries. □

Which Newborns in New York City Are at Risk for Special Education Placement?

Doris Goldberg, MD, MPH, Margaret McLaughlin, MD, MPH, Margaret Grossi, MD, MPH, Alex Tytun, PhD, and Steve Blum, PhD

ABSTRACT

In this study of 162 third graders in New York City public schools, we found that slightly over half of the children in special education were males who had Medicaid coverage at birth and mothers with medical conditions or adverse health habits noted on the birth certificate; two thirds of the children with this combination of characteristics actually were placed in special education. These findings suggest that newborns at risk for later learning disabilities can be targeted to receive preventive interventions. (*Am J Public Health.* 1992;82:438–440)

Introduction

Public Law 99-457 supports a national initiative to establish early identification and service systems for children with special needs from birth to 3 years of age. Some of the children who will require special education services in the early grades of school can be detected as having special needs in the first 3 years of life. Some may have medical conditions associated with cognitive difficulties, and others may have health or social risks for later learning problems. In this pilot study, we linked the educational placement records of third graders in the New York City public school system with information on their birth certificates and retrospectively analyzed the association of special education placement with characteristics recorded on birth certificates. The identification of newborns at risk can supplement the current identification of children with special needs and allow children to be targeted for preventive interventions in the preschool years to reduce their need for costly special education services in school.

A combination of reproductive health and sociodemographic variables was found to be the strongest predictor of school failure when Ramey et al.[1] studied birth certificate data from North Carolina. Escalona[2] found increased jeopardy for socially disadvantaged children with biological risks. Chamberlin[3] recently concluded that perinatal factors have a decreasing impact and environmental factors have an increasing impact on developmental status as children progress from birth to the age of 7. Palfrey et al.[4] found an association between mother's educational attainment and early diagnosis of high- and low-prevalence learning disorders in children.

Methods

Data for this study consisted of linked birth and school records of 162 third graders attending New York City's public schools. Access to school health records was obtained in three elementary schools located in three demographically distinct school districts: Bedford-Stuyvesant, Coney Island, and Staten Island. All third graders in special education classes (n = 45) were treated as "cases"; more than twice this number (n = 117) were randomly selected from the general education third-grade populations in the same schools and treated as "controls." The case group was broadly defined to include the mildly retarded, the emotionally disturbed, and those requiring speech or other therapies to foster learning. Third graders were chosen because placement in special education classes is generally arranged at the end of second grade for children who exhibit learning or behavioral difficulties in the general classroom setting.

The dependent variable in this study was educational placement status; the predictor variables were obtained primarily from birth certificates, although additional information was gathered from available

school records. For example, "medical complications" is a constructed variable representing maternal pregnancy complications, chronic medical conditions preceding pregnancy, adverse health habits (e.g., smoking, alcohol or substance abuse), or a combination of these factors. "Changed school district" is a variable derived by comparing the community school district in which the residence address stated on the birth certificate is located with that where the child is actually enrolled in school; it is a rough indicator of the within-city mobility of children with special needs.

Results

Table 1 shows the percentage distribution of special- and general-education children across 12 variables; the distribution of the total number of live births in New York City during 1980 (the year of

[a]Information was unavailable for one subject.

birth for the majority of the study sample) across the same variables is shown for comparative purposes. Special-education children were far more likely to be Black males whose unmarried mothers lacked formal education beyond high school and who had Medicaid coverage at the time they gave birth.

Presented in Table 2 are some of the same variables stratified by both race and educational placement. "Sex," "mother's education," and "medical complications" continue to show a strong association with educational placement (i.e., the pooled odds ratios exceed 2) when the effects of race are controlled statistically. However, the degree of association between educational placement and Single Mother or Medicaid Coverage is so different between racial groups as to dictate against estimating a common odds ratio. Among Black children in this study, Medicaid coverage appears to be unrelated to educational placement.

Stepwise linear logistic regression (Table 3) was performed with 12 key variables to identify a set of minimally redundant variables that could best predict educational placement. Regardless of whether forward selection or backward elimination methods were employed, or whether variables were treated as categoric or numeric, the same three factors emerged: sex of child (SEX), Medicaid coverage at time of birth (MEDICAID), and one or more medical complications at birth (MEDCOMP). Because this function was estimated solely for purposes of prediction, no substantive interpretation will be given to the regression coefficients.

Classifying children by their sex, their mother's Medicaid eligibility, and the presence or absence of medical complications at birth enabled us to correctly identify 25 out of 45 children in special education and, less importantly, 99 out of 116 children in general education.

Discussion

This pilot study suggests that certain health factors and sociodemographic characteristics that can be identified at birth are strongly associated with third graders' educational placement. It would be worthwhile to apply a similar kind of analysis to a much larger sample that would be more representative of the city's 32 community school districts. Specific risk factors can be expected to vary within diverse pupil populations, as was demonstrated in the present study with racial stratification.

Sex, Medicaid coverage, and medical complications, taken together, were the risk factors most strongly associated with educational placement in the regression analysis. Although controversy remains as to whether biological or sociological factors determine why more boys than girls end up in special education classes,[5] extensive data suggest that males are more likely to be candidates for special education for biological reasons.[6]

The preliminary results presented in Table 4 imply that one in every three children whom we can identify as being at risk for special education will eventually require it. This implication, in turn, suggests that prognostic methodologies such as the one described here can be employed to supplement the traditional indicators for medical assessment, rather than to replace accepted methods for screening and evaluating newborns and preschoolers with known biological risks. Classification procedures like those employed here can nevertheless aid in more precisely identifying newborns who should be followed continuously and screened periodically and who should receive supportive services. Such interventions should significantly reduce the chances that early vulnerability will progress to later disability, which will be more difficult and costly to treat. □

The Lowest Birth-Weight Infants and the US Infant Mortality Rate: NCHS 1983 Linked Birth/Infant Death Data

Mary D. Overpeck, MPH, Howard J. Hoffman, MA, and Kate Prager, ScD

ABSTRACT

The National Center for Health Statistics Linked Birth and Infant Death Data Set, 1983 birth cohort, shows that infants weighing less than 750 g, comprising only 0.3% of all births, account for 25% of deaths in the first year of life and for 41% of deaths in the first week. If interventions had prevented the death of these very small babies, the infant mortality rate would have been 8.3 per 1000 live births instead of 10.9, and the Black/White mortality differential would have been reduced by 25%. (*Am J Public Health*. 1992;82:441-444)

Introduction

Low- and very low-birth-weight perinatal mortality has decreased dramatically over the past few decades.[1,2] California linked birth and death certificates show that the decline in perinatal mortality rates in the 1970s occurred primarily from improvements in the survival of infants born at weights above 750 g.[3] Virtually no change was observed for infants weighing under 751 g, and only a small decrease was observed for infants weighing between 751 and 1000 g. Prospective studies of reproductive outcomes also show higher losses among fetuses from 16 to 24 gestational weeks than among fetuses from 25 to 29 gestational weeks, with clinical assessment of very poor viability for fetuses under 500 g or 22 weeks of fertilization age.[4-8]

The Linked Birth and Infant Death Data Set, 1983 birth cohort, from the National Center for Health Statistics (NCHS) is the first national linkage of individual birth and death certificates since 1960.[9,10] Linkage overcomes limitations of infant mortality rates (IMRs), in which the numerator is based only on annual counts of death certificates; it also permits calculation of mortality rates by birth weight for the whole United States. A 1980 analysis based on linkages by individual states shows the impact of very low-birth-weight (VLBW) infants on the US IMR. This tabular data set, however, did not include births under 500 g or allow comparisons of infants born at weight intervals smaller than 500 g.[11]

The present analysis focuses on individually linked data for the least viable infants (those weighing less than 500 g and those weighing 500 to 749 g), their contribution to the total IMR, and the rate and age at which they die. Black and White births are analyzed separately because of differential rates of extremely low-weight births and attributable proportions of deaths.

Methods

The methodology to create the 1983 linked file is described in both the NCHS Public Use Data Tape Documentation and a working paper.[12,13] The file contains linked records for *all* infants born in 1983 in the United States who died in 1983, or in 1984 before their first birthday.

Records were linked for 39 683 resident infant deaths, 98.4% of all infant deaths occurring in the United States during the time specified. Analysis of the 651 unlinked death certificates shows them to be similar to the linked certificates in terms of race and age at death. If no death certificate was filed, an infant with a birth certificate was assumed to have survived. Specific rates may be slightly understated owing to unlinked records or to missing information on the linked records. Birth weight is missing for 2.9% of linked infant deaths and for 0.1% of all births. Birth weight is used here instead of gestational age because it is more completely and accurately reported.[14,15]

Differences larger than 2% in Figures 1 and 2 are statistically highly significant based on Fleiss' confidence interval procedures.[16] Otherwise, statistical significance has been assessed using chi-square tests on relative risk (RR) estimates, as discussed for Table 1.

Results

Forty-three percent of all infant deaths came from 1.2% of all live births, the VLBW infants weighing less than 1500 g (Table 1). The majority of deaths among VLBW infants came from those weighing 500 to 749 g and those weighing less than 500 g, with 25% of total deaths coming

from the 0.3% of births at these lowest weights (14.7% from White births, 9.2% from Black births). Infants weighing 500 to 749 g had a mortality rate more than three times the rate of those weighing 750 to 1499 g; those weighing under 500 g had nearly four times the rate. Mortality rates with weight not stated indicate a bias toward the smallest infants.

Higher birth-weight-specific mortality rates for Blacks occurred only at normal weights (RR = 1.66) and unknown weights (RR = 2.16). Relative risks of death for Black infants compared with White infants were 0.85 at 1500 to 2499 g, 0.77 at 750 to 1499 g, 0.93 at 500 to 749 g, and 0.98 at under 500 g. Relative risks indicate better survival only for those Black infants weighing between 750 and 1499 g and 1500 and 2499 g.

The attributable proportion of Black deaths from births weighing less than 750 g was 33%, compared with 21% for White deaths (Figure 1). Infants born weighing 750 to 1499 g contributed similar proportions of deaths within each race. Because there were 5.3 times more White births than Black births weighing 2500 g or more, compared with only 1.5 times more White births weighing less than 500 g (Table 1), a much larger fraction of Black deaths resulted from extremely low weights.

The risk of death was highest in the early neonatal period (from 0 to 6 days of life), especially for VLBW infants (Table 2). The early neonatal mortality rate increased exponentially as birth weight decreased by 250-g intervals. The late neonatal and postneonatal mortality rates also increased as birth weight decreased. The small numbers of late neonatal and postneonatal deaths reported for infants weighing less than 500 g may have produced unreliable rates. Survival decreased rapidly as birth weight decreased.

Births weighing less than 750 g resulted in 41% of all early neonatal deaths (Table 3). Of those, 18% were attributable to births weighing less than 500 g. Deaths of the smallest infants contributed to more early neonatal mortality among Blacks than among Whites (Figure 2). Twenty-five percent of Black and 15% of White early neonatal deaths were due to infants weighing <500 grams at birth. Infants weighing less than 750 g contributed 53.2% of Black deaths and 36.4% of White deaths occurring before the first week of life.

Discussion

Changes have occurred both in the reporting of vital statistics on extremely premature infants and in clinical practice affecting fetal and infant survival. Although there are problems with the reporting of deaths among the very smallest infants,[17–19] there is also an increasing number of live-born deliveries that previously might have been fetal deaths.[20–22] Although low-weight births are better reported in the United States than in most developed countries,[23] new initiatives are still needed to improve data quality.[24–26]

Different interpretations of the World Health Organization's definitions of live birth and fetal death in borderline situations affect the reporting of these occurrences in the 500-g range.[27–29] Comparison is complicated by different underlying distributions of extremely low-weight births among races as well as among states and countries.[3,30–34] Adjusting for differences in birth-weight distributions would improve precision in analyses of differences by race or region in infant mortality.[35–37]

Several reports have emphasized that reductions in infant mortality and

[b]Includes races other than White and Black and "not stated" weights.
[c]Deaths for which birth weight was not stated on the linked birth certificate.

Black/White differentials will require interventions affecting the lowest weight categories.[3,9,22,38,39] Birth-weight-specific data improve the ability to evaluate such interventions.[40–41] If interventions had prevented deaths of infants weighing less than 500 g in 1983, the IMR of 10.9 per 1000 live births would have been 9.8 (9.3 reduced to 8.5 for Whites, and 18.9 reduced to 16.3 for Blacks). Prevention of deaths among infants weighing less than 750 g would have lowered the IMR to 8.3 (7.3 for Whites and 12.8 for Blacks). Finally, the Black/White mortality differential would have been reduced by 25%. □

An Epidemiological Comparison of Mexican-American and White Non-Hispanic 8th- and 12th-Grade Students' Substance Use

Ernest L. Chavez, PhD, and Randall C. Swaim, PhD

ABSTRACT

Surveys of drug and alcohol use were conducted with a national probability sample of 8th- and 12th-grade Mexican-American and White non-Hispanic youth. The drug and alcohol epidemiology is representative of US Mexican-American youth residing in communities with populations of 2500 or more, at least 10% of whom are Mexican Americans. Mexican-American 8th graders reported generally higher rates of use than White non-Hispanics based on lifetime prevalence and use in last month. They also reported higher frequency of high-risk drug behaviors. The pattern was reversed among 12th-grade students. The impact of differential school dropout rates is discussed as a probable cause for this reversal. (*Am J Public Health.* 1992;82:445–447)

Introduction

Epidemiological studies of Hispanic substance use have focused on use in specific states[1] or specific communities,[2,3] or on use among youth in Puerto Rico.[4,5] In recent reviews of Hispanic drug use, Chavez and Swaim[6] and De La Rosa and colleagues[7] conclude that there are important differences in the drug use of subgroups of Hispanics and that there are substantial gaps in our knowledge of both the epidemiology and etiology of Hispanic substance use. The current study addresses one of the important gaps by presenting normative data on substance use among 8th- and 12th-grade Mexican-American youth. Mexican-American (MA) youth are compared with White non-Hispanic (WnH) youth residing in the same communities.

Method

Sampling Procedure

A representative national sample of 8th- and 12th-grade Mexican-American students was selected from an initial sampling frame of all US communities with populations of 2500 or higher, at least 10% of which was Mexican American (based on the 1980 US Census). Communities were chosen at random throughout the range of population densities so that the sample represents urban, midsized, and rural communities.

Once a community was chosen, individual schools within the community were selected with probabilities equal to the proportion of Mexican Americans within each school. A total of 26 middle schools and 25 high schools were surveyed over the 3-year project.

Subjects

All available students within the class grade in each school were surveyed. Those not surveyed were absentees or refused to participate (less than 1%). Eighty-two percent of all enrolled students completed surveys. This amounted to 2530 8th-grade and 1837 12th-grade MA students and 1547 8th-grade and 2243 12th-grade WnH students attending the same schools. Data on enrollment by ethnicity were not available from all schools, so calculation of the percentage surveyed by ethnic group was not possible. For 8th-grade students, 48.7% were female; for 12th-grade students, 51.0% were female.

The Survey

Students completed the American Drug and Alcohol Survey™, a self-administered survey that measures current and lifetime use of 21 substances. This instrument has been administered to more than 300 000 students, and much of its development has been with minority adolescents. It has been demonstrated to be highly reliable.[8,9]

Results

Lifetime Prevalence

Lifetime prevalence provides a comparative measure between populations of the degree of exposure to an individual drug and of the percentage of individuals who have been willing to at least try the substance. Lifetime prevalence rates for 8th- and 12th-grade students are in Table 1. MA 8th graders reported significantly higher lifetime prevalence rates for marijuana, cocaine or crack, crack only, heroin, steroids, and cigarettes. WnH 8th graders reported higher rates for alcohol, stay-awake pills, diet pills, and smokeless tobacco. WnH 12th graders reported significantly higher lifetime prevalence across a wide range of substances includ-

ing alcohol, ever drunk, marijuana, inhalants, nitrites, uppers, legal stimulants, tranquilizers, LSD, other psychedelics, other narcotics, stay-awake pills, steroids, cigarettes, and smokeless tobacco.

Use in Last Month

The results for last 30-day prevalence are in Table 2. MA 8th graders reported significantly higher rates of use than WnH 8th graders for marijuana, inhalants, nitrites, and crack. Among 12th-grade students, rates were higher among WnH youth for nearly all substances and were significantly so for alcohol, ever drunk, marijuana, uppers, LSD, cigarettes, and smokeless tobacco.

Some youth who use drugs and alcohol will engage in high-risk drug behaviors that are usually part of a pattern associated with heavy substance involvement and may include exposure to either increased health risks due to the use of needles or accident risks due to heavy intoxication. The percentage of youth reporting high-risk substance behaviors is presented in Table 3.

MA 8th graders reported significantly higher rates of high-risk behaviors across a number of categories, including using substances when alone, sharing a needle, combining use of alcohol and marijuana, and using two other drugs at once. Among 12th graders, WnHs reported higher levels of high-risk behaviors in nearly all categories, and significantly in using substances when alone, staying high for several hours, and combining use of multiple substances.

Discussion

These results provide normative rates of drug use epidemiology for Mexican-American youth residing in communities with populations of 2500 or more. These data also supply baseline rates so that comparisons can be made with other racial groups, other Hispanic subgroups, and subgroups of Mexican-American youth (e.g., barrio youth).

There was a general trend among 8th-grade students toward higher use by MAs. The 12th-grade results reveal a general trend toward higher use among WnHs. This shift was also present for rates of high-risk drug behaviors. Several hypotheses may explain these reversals of drug-use rates between the 8th and 12th graders.

First, these differences may be due to cohort effects. But given the gradual decline in adolescent substance use over the past several years, this would mean that whatever factors are leading to this reduction are working selectively on WnH youth and not on MA youth. This scenario is not likely.

A more likely explanation is the dropout effect. Rates of drug use are generally higher for dropouts, and the dropout rate is significantly higher for Hispanics. Those MA youth who are most likely to use and abuse drugs are, therefore, absent from the 12th-grade sample. Chavez et al.[10] reported preliminary results showing that

MA dropouts have higher lifetime prevalence rates than WnH dropouts for many drugs, and that these rates are higher than those reported by either MA youth doing well in school or MA youth who are "educationally at risk." Any attempt to estimate the overall drug use rate of adolescents that does not take into account the dropout problem may be seriously underestimating the extent of the drug use problem within this age group. Further epidemiological research on drug use with various racial groups that includes drug use data on dropouts is needed to determine how dropping out of school affects substance use estimates. □

TABLE 3—Lifetime High-Risk Substance Behaviors

	8th Grade		12th Grade	
	WnH	MA	WnH	MA
High-Risk Behavior	(n = 1547)	(n = 2530)	(n = 2243)	(n = 1837)
Got drunk alone	9.3[a]	11.6[a]	23.0[a]	14.8[a]
Used marijuana alone	5.6[a]	11.7[a]	17.1[a]	13.2[a]
Used other drug alone	6.1[a]	8.3[a]	11.8[a]	9.4[a]
Needle/cocaine	2.0	2.6	1.3	1.1
Needle/heroin	2.3	2.8	1.3	1.2
Shared a needle	1.6[a]	2.7[a]	0.9	1.1
Stayed high 7+ hours	4.4	5.6	16.1[a]	9.9[a]
Used alcohol and marijuana	8.5[a]	12.9[a]	36.7[a]	26.9[a]

Analyzing the Effect of Prenatal Care on Pregnancy Outcome: A Conditional Approach

Michael H. Malloy, MD, MS, Tzu-Cheg Kao, PhD, and Y. J. Lee, PhD

ABSTRACT

We used vital statistics data to examine the effect of the time of entry into prenatal care relative to the gestational age of delivery on pregnancy outcome. Early entry into prenatal care was associated with better outcomes only in women who delivered at 37 through 42 weeks of gestation. We are concerned that the evaluation of the effect of prenatal care using vital statistics data may be questionable because of the problems inherent in the data. (*Am J Public Health.* 1992;82:448–450)

Introduction

Vital statistics data is a readily available source of information on prenatal care usage in the United States. How to examine vital statistics and other types of data for the effect of prenatal care on pregnancy outcome has generated a number of different methodologies.[1–4] One of the difficulties encountered in using such data has been the problem of overcoming the preterm bias effect. The preterm bias effect is associated with observing better outcomes in women who receive prenatal care than in women who receive no care. This artifact occurs because women receiving no care may deliver prematurely and may not have an opportunity to enroll in prenatal care.[5] By conditioning the effect of the age of entry into prenatal care on the gestational age of delivery, however, the preterm bias effect can be avoided. Nonetheless, other problems encountered in vital statistics data may invalidate the results of the conditional approach.

In this study, we demonstrate the effect that the possible misclassification of gestational age in vital statistics data has on the interpretation of the conditional approach and discuss the problematic nature of the evaluation of prenatal care.

Methods

The data for this analysis were obtained from linked birth and death certificates from Missouri for 1980 through 1984. The variables used in the analysis were the gestational age at which prenatal care was initiated (self-report and limited to the first 36 weeks of pregnancy), the gestational age at delivery (based on last menstrual period), the outcome (stillbirth, infant death, or alive at 1 year), race (Black or non-Black), birth number (multiple vs single), parity, maternal age, and maternal education. We used only those records that involved gestational ages of greater than 19 weeks and less than 51 weeks. Of the 387 173 records available, 375 858 (97.1%) were used for the unadjusted analyses and 374 244 (96.7%) were used for the adjusted analyses.

The association of the gestational age of entry into prenatal care with pregnancy outcome was examined relative to the gestational age of delivery. Outcomes (stillbirths or infant deaths) are presented as death rates (percentage dead). We calculated odds ratios for stillbirths or infant deaths by logistic regression models adjusted for race (Black vs non-Black), multiple births (multiple vs single), (0 parity and parity greater than 3 compared with parity 1 through 3), maternal age (less than 18 and greater than 34 compared with 18 through 34 years), and maternal education (less than 12 compared with greater than 12 years). Mantel-Haenszel tests for linear trends were carried out for mortality rates over the gestational ages of entry into prenatal care.[6] Furthermore, we adjusted our results by declaring newborns that exceeded the 90th percentile birth-weight standards for gestational age reported by Arbuckle[7] as misclassified. All computations were carried out using SAS®.[8]

Results

By conditional analysis, the risk (percentage of mortality) of stillbirth or infant death for those women who delivered at 25 weeks to 28 weeks of gestation and who entered prenatal care between 1 and 4 weeks was greater than the risk of still-

[a] Newborns weighing over the 90th percentile for gestational age, based on the growth standards reported by Arbuckle,[7] were deleted.
[b] Ninetieth percentile weights were not available of gestations greater than 42 weeks, therefore the rates in this table are the same as those presented in Table 1 for outcomes occurring after 42 weeks.
[c] Mantel-Haenszel test for linear trends in mortality rates excluding those with no care.[6]

birth or infant death for women who delivered at 25 to 28 weeks and received no care (Table 1). The adjusted odds ratio was 1.67 (95% confidence interval = 1.03, 2.71). This higher risk of mortality in early entrants delivering before 29 weeks, however, appears to be an artifact of the misclassification of the gestational age of the survivors. This is apparent when newborns with weights greater than the 90th percentile for gestational age were not included in the analysis (Table 2). The declining mortality rates as the gestational age of entry into prenatal care increased observed in Table 1 are not apparent in Table 2.

For women delivering after 36 weeks of gestation, early entry into prenatal care was a marker for optimal pregnancy outcome. The risk for stillbirth or infant death increased progressively for those delivering at 37 through 42 weeks from a low of 0.60% for those who entered prenatal care at 1 through 4 weeks to a high of 2.96% for those who received no care (Table 1). The results for this group in Table 1 are similar to the results reported in Table 2.

Discussion

As Tyson et al. state, "the value of prenatal care has been difficult to establish."[4] When the time of entry into prenatal care is assessed relative to the time of delivery, several interpretations about the association of prenatal care with pregnancy outcome become available. For example, it appears that in women who delivered at less than 29 weeks and who entered prenatal care in the first trimester, there were more adverse pregnancy outcomes than in those women who delivered at this time and were not in prenatal care. We believe this is an artifact. Kramer et al. have reported a systematic underestimation of gestational age in infants born before 37 weeks when the gestational age is based solely on the last menstrual period.[9] When infants weighing over the 90th percentile for their gestational age were eliminated from the analysis, there were no significant trends in mortality rates over the gestational age of entry into prenatal care except for those women delivering

between 37 and 42 weeks. Whether prenatal care for these women is responsible for the better outcome of the early entrants cannot be determined. Early entry may reflect as much on the healthy behavioral characteristics of these women as it does on any effect of prenatal care.

The evaluation of prenatal care is a complex problem. The incorrect assignment of gestational age affects significantly the results of any perinatal analysis and continues to be a major problem for which no solution is readily available. As a result, there is no ideal model available to assess the association between prenatal care and pregnancy outcome. Because of the substantial problems associated with observational data, the use of randomized trials of different modes of care deserves increased consideration as the optimal method for gaining a greater understanding of the efficacy of prenatal care. □

The Safety of Home Birth: The Farm Study

A. Mark Durand, MD, MPH

ABSTRACT

Pregnancy outcomes of 1707 women, who enrolled for care between 1971 and 1989 with a home birth service run by lay midwives in rural Tennessee, were compared with outcomes from 14 033 physician-attended hospital deliveries derived from the 1980 US National Natality/National Fetal Mortality Survey. Based on rates of perinatal death, of low 5-minute Apgar scores, of a composite index of labor complications, and of use of assisted delivery, the results suggest that, under certain circumstances, home births attended by lay midwives can be accomplished as safely as, and with less intervention than, physician-attended hospital deliveries. (*Am J Public Health.* 1992;82:450–452)

Introduction

Despite a sizable body of literature on the subject, the authors of two recent reviews have concluded that a final judgment regarding the relative safety of home birth still cannot be made.[1,2]

This study compares the outcomes of a cohort of 1707 planned lay midwife–attended home births from the Farm midwifery service in rural Tennessee with the outcomes of a sample of physician-attended hospital births derived from the 1980 US National Natality/National Fetal Mortality Survey (NNS/NFMS). This is the largest comparative study of a cohort of home births yet published.

Previous studies of home birth safety underscore the importance of having explicit comparison groups (rather than of being strictly descriptive),[1] of considering planned and unplanned home births separately,[2–4] of tracking intrapartum hospital transfers of intended home births (and attributing the outcome to the home birth group),[5] and of controlling for the effects of birth weight, type of delivery attendant, and demographic characteristics of the mother.[6,7] All these issues have been addressed in this study.

Standards of prenatal care at the Farm are modeled to the recommendations of the American College of Obstetricians and Gynecologists. Deliveries are conducted without analgesia, however, and great emphasis is placed on meeting the emotional needs of the family. Several family members and friends are commonly in attendance and are encouraged to take an active role in the birth.[8] In addition, the laboring woman is encouraged to stay off her back and remain physically mobile through labor and delivery. In the absence of signs of fetal distress, women are permitted to labor beyond 24 hours, occasionally for 2 to 3 days. They are also encouraged to eat and drink during labor in the belief that this allays maternal exhaustion and the need for operative delivery.

This paper was submitted to the journal November 11, 1990, and accepted with revisions July 9, 1991.

A hospital with surgical facilities is located about a 20-minute drive from the community.

Methods

A retrospective cohort of 1707 births derived from all pregnancies accepted for care at the Farm between January 1971 and June 1989, except those that aborted spontaneously prior to 28 weeks gestational age and 54 who were lost to follow-up, was studied. The outcomes of all these births were attributed to the Farm group, whether or not delivery was ultimately accomplished at home (Table 1).

Women with preexisting diabetes or hypertension, Rh negative blood with positive antibody screen, weight greater than 135 kg, and hematocrit on intake lower than 28 were considered ineligible for care at the Farm. In addition, before 1985, women with prior cesarean section were also considered ineligible.

The NNS/NFMS is a probability sample of births in the United States in 1980 for which a birth or fetal death certificate was filed. Low birth weights (less than 2500 g) and fetal deaths were deliberately oversampled to allow more detailed study of them.[9] Stillborn infants of less than 28 weeks gestational age (or weight of 1000 g) were not included.

Of the 16 327 births that ultimately constituted the NNS/NFMS, an additional 2294 were deleted from this study to eliminate those that were attended by nonphysicians, those who delivered out-of-hospital, those with no prenatal care, and those in which the mother had prenatal risk factors that were used as exclusion criteria at the Farm (Table 1).

The design effect created by differential sampling and losses due to lack of data across the strata (fetal deaths, live births of low birth weight, other live births) in the NNS/NFMS was compensated for by assigning weighting coefficients (0.0131, 0.4227, and 1.8844, respectively) to the observations in each of the three strata. The coefficients are normalized such that the average coefficient of a single observation is 1.0, which is the coefficient assigned to observations in the Farm group. These coefficients were applied in the analyses described below.

Data for both groups were obtained by retrospective review of medical records.

The principal independent variable of this study is the intended site of delivery. The dependent variables are measures of pregnancy outcome defined as (1) death of the fetus at birth weight greater than 1000 g or at 28 weeks gestational age, or death of a live born infant aged less than 28 days; (2) a 5-minute Apgar score of less than 7; (3) use of forceps, vacuum, or cesarean delivery; and (4) occurrence of excessive bleeding during labor, labor of greater than 24 hours duration, neonatal birth injury, or neonatal respiratory distress. The effect of intended site of delivery on each outcome was examined via multiple logistic regression equations, which also contained terms for potential confounders.

Of these potential confounders, maternal education and number of prenatal visits were treated as continuous variables. Birth order (1, 2 to 4, greater than 4), maternal age (younger than 18, 18 to 34, older than 34), birth weight (less than 2500 g, 2500 to 4000 g, greater than 4000 g), and smoking during pregnancy (yes, no) were categorized.

The power to detect odds ratios of 1.5 or greater for the delivery type and labor complications outcomes exceeds 0.99. For low 5-minute Apgar scores, the corresponding power is 0.75 (0.99 for odds ratio of 2 or greater). For perinatal mortality, this study has a power of 0.62 to detect an odds ratio of 1.5 (0.98 for odds ratio of 2 or greater). All power calculations presume two-sided comparisons.

Results

Demographic characteristics of women in the two groups and transfers to hospital care from the Farm group are summarized in Tables 2 and 3.

No significant differences between the two groups regarding fetal and neonatal death, labor-related complications, or low 5-minute Apgar scores were detected, regardless of whether the comparisons were crude or adjusted for confounders (Table 4). Rates of assisted deliveries were very low in the Farm group (2.11%) compared with the NNS/NFMS sample (26.60%), a difference that is statistically significant at the P = .01 level. The casarean section rate was 1.46% at the Farm vs 16.46% in the NNS/NFMS sample (Table 4).

The causes of death for the 17 deceased neonates and stillbirths in the Farm group are listed in Table 5. There were no maternal deaths in the Farm group.

Discussion

In this study, lay midwife–attended home births appear to have been accomplished with safety comparable to that of conventional births. Furthermore, the proportion of deliveries in which opera-

tive assistance was required was much smaller in the Farm group (though a fraction of this discrepancy may have been due to the fact that, prior to 1985, women who had had previous cesarean deliveries had been excluded from care by Farm midwives).

Stratifying both groups by birth weight or parity, comparing the entire Farm set to the NNS/NFMS subset of births from nonmetropolitan southern US areas or of White mothers only, and breaking the Farm set into groups by year of delivery did not appreciably alter the results (data not shown). Thus, differences in demographic characteristics or changes in technology over time do not appear to explain the findings. Of course, other factors such as diet (many mothers in the Farm group were vegetarians), occupational profile, and psychological differences among those electing home birth could help explain the observed results.

Observer bias could also have distorted the results. (The likelihood of a complication or outcome being noticed and recorded may be different for midwives than for physicians.) However, the results regarding perinatal deaths, in particular, are hard to ascribe to observer bias.

The possibility that some outcomes that were not examined in this study may be worse among those delivering at home and that other groups of attendants may not perform as well as the Farm midwives should also be noted.

Hospital births have a safety advantage in cases in which life-saving technology is immediately required. There is some evidence, however, that elective interventions, which are used more frequently in-hospital, may increase the risk of various adverse outcomes in low-risk women.[10–17]

In addition, it is possible that the unfamiliar setting and the presence of unfamiliar personnel, the limited presence and role of family members, and the restricted freedom of movement of the laboring woman may all create an atmosphere at a hospital birth that undermines self-confidence and encourages passivity on the part of the laboring woman, diminishing her ability to deliver spontaneously. Recent work demonstrating the beneficial effect of supportive female attendants (doulas) during labor, highlights the importance of such intangibles.[18]

The results of this study suggest that, for relatively low-risk pregnancies, home birth with attendance by lay midwives is not necessarily less safe than conventional (hospital-physician) delivery. Support by the medical and legal communities for those electing, and those attending, home birth should not be withheld on the grounds that this option is inherently unsafe. □

TABLE 4—Association between Intended Site of Delivery and Selected Pregnancy Outcomes

Skilled Nursing Facility Care for Persons with AIDS: Comparison with Other Patients

James H. Swan, PhD, A. E. Benjamin, PhD, and Andrew Brown, MD

ABSTRACT

We compared average daily hours of care for patients with and without acquired immunodeficiency syndrome (AIDS) in a hospital-based skilled nursing facility. Patients with AIDS averaged over an hour more direct nursing care per patient day (6.5 vs 5.4 hours). These findings support other reports of greater nursing time and higher costs of caring for nursing home patients with AIDS. (*Am J Public Health.* 1992;82:453–455)

Introduction

Skilled nursing facility (SNF) care for persons with acquired immunodeficiency syndrome (AIDS) (PWAs) is limited but will likely grow.[1] As the postdiagnosis life expectancy of PWAs increases[2] and greater numbers of PWAs find no other locus of care,[3–5] SNFs should become accepted parts of an AIDS continuum of care.[6–8] AIDS poses major challenges to providers that are inexperienced with PWAs[9,10] and the populations from which they derive,[11] and that are not equipped to deal with special care needs[9] or special precautions and infection controls.[10]

PWAs are generally thought to be costlier than traditional nursing home patients[12,13] because they need different, more complex, and higher volumes of care.[10] Kerschner reports that PWAs in the final months of life require, on the average, 7 hours of nursing home care daily.[14] Adams[15] reports that PWAs require an average of over 5 hours' direct intermediate care facility–level nursing care daily. Swan and Benjamin report an average daily total nursing time of 6.5 hours (5.4 hours direct time) for PWAs in a freestanding AIDS-dedicated SNF[1]; this time approaches the 6.5 to 7.5 hours of care required daily for functionally dependent nursing home patients with complex needs.[16]

Some industry observers have argued that PWAs' need for heavy care has been overstated,[17] but no research has directly examined the relative costs of SNF care for PWAs versus "traditional" nursing home populations. This study begins to fill the gap, using comparative data on AIDS and non-AIDS care in a single hospital-based SNF in California.

Methods

In our study of care for PWAs in two Northern California SNFs with dedicated AIDS beds, a random sample of 29 non-AIDS patients was drawn from a hospital-based SNF between August 18 and December 31, 1987. (The other SNF served PWAs only.) The sample was drawn from two wards that also cared for AIDS patients—an oncology ward and a general ward. These 29 patients averaged 51 days of care per patient, compared with 41 days per patient for the 20 PWAs receiving care in the SNF in the same period.

A major issue was whether nursing hours were greater for PWAs than for others. Nursing hours were measured in two ways: (1) monthly nursing personnel time divided by days of care provided that month, and (2) daily direct plus indirect nursing time per patient attributed to nursing procedures recorded using GRASP,[18]

At the time of this study, all authors were with the Institute for Health Policy Studies, University of California, San Francisco. James H. Swan is now with the Health Care Administration Program, California State University, Long Beach, Calif.

This paper was submitted to the journal December 11, 1990, and accepted with revisions June 10, 1991.

TABLE 1—Analysis of Variance: Average Daily Direct Nursing Care Hours for Persons with AIDS (PWAs, n = 20) and Non-AIDS Patients (n = 29) in a Skilled Nursing Facility

	Mean	SEM
PWAs	6.501	0.263
Non-AIDS patients	5.434	0.195
$R^2 = .184$		
Mean square between = 1278.18		
Mean square within = 120.33		
$F(1, 47) = 10.623$, $P < .01$		

Note. Patient days for PWAs = 821; patient days for non-AIDS patients = 1486.

TABLE 2—Analysis of Variance: Average Daily Direct Nursing Care Hours for Persons with AIDS (PWAs) and Non-AIDS Patients in a Skilled Nursing Facility, by Ward

	Mean[a]	SEM
Oncology ward		
PWAs (n = 11)	6.695	0.341
Non-AIDS patients (n = 15)	5.146	0.354
General ward		
PWA (n = 9)	6.212	0.415
Non-patient (n = 14)	5.561	0.341
$R^2 = .215$		
Mean square between = 497.313		
Mean square within = 120.924		
$dF(3, 45) = 4.11$, $P < .05$		

Note. Patient days = 491 for PWAs on the oncology ward, 455 for non-AIDS patients on the oncology ward, 330 for PWAs on the general ward, and 1031 for non-AIDS patients on the general ward.
[a]The difference between mean hours of care for PWAs and mean hours of care for non-AIDS patients on the oncology ward was significant at $P < .01$.

adapted to the SNF. (GRASP is proprietary to FCG Enterprises, Inc, Morgantown, NC.) A comparison showed close agreement between the two methods.[1]

Because patients differ in numbers of days of care and because of a general concern for daily resource use, daily nursing hours are reported. Analysis of variance was employed to test differences in nursing hours.

Findings

PWAs in the hospital-based SNF were more severely ill and functionally debilitated than were PWAs in the community. Two thirds scored 30 or lower on the Karnofsky Performance Status Scale; three fourths had diagnoses of dementia; half were dependent in all activities of daily living; three fourths were discharged by reason of death. Three fourths listed their sexual orientation as homosexual; one third reported intravenous drug use; half were aged 40 or older. Except in age, these PWAs were relatively similar to PWAs nationwide.[19,20]

An analysis of variance was conducted to compare average daily direct nursing time for PWAs and non-AIDS patients (Table 1). PWAs averaged over an hour more direct nursing time (6.5 hours) than did non-AIDS patients (5.4 hours). The latter group still represents high resource use, far greater than the 3.0 total nursing hours defining SNF care in California. This difference is attributable to the SNF's being hospital-based and thus associated with heavy care.

Although the small sample size restricted analytic power, limiting the ability to control for covariates, an analysis of variance was used to compare differences between PWAs and non-AIDS patients on the oncology ward and the general ward (Table 2). On the oncology ward, PWAs averaged over 1.5 nursing hours per day more than did other patients (6.7 vs 5.1 hours). On the general ward, the difference was about 0.7 hours, which, because of small numbers and wide variation among patients, was not significant. PWAs averaged less nursing time on the general ward than on the oncology ward, whereas non-AIDS patients received more nursing care on the general ward; these differences were not significant.

Discussion

It is generally thought that PWAs in nursing homes require more and costlier care than do non-AIDS patients. Judging by the data presented here on average nursing time per patient day, this argument appears to be true at a hospital-based SNF in California.

Our major finding is that PWAs received about 20% more nursing time than did other SNF patients. We found a difference of 1 hour per day (1½ hour on the oncology ward) in a hospital-based SNF, where all care is likely to be far heavier than that at freestanding SNFs, which constitute the majority of such facilities.[21]

Because not much is known about SNF care for PWAs, we cannot say whether our sample is similar to other groups of PWAs in nursing homes. The level of direct nursing time per patient day for non-AIDS patients at this SNF is double the level defining SNF care in California. Both PWAs and non-AIDS patients appear to approximate the designation of functionally dependent nursing home patients with complex needs.[16]

Despite expectations that hospital-based SNFs, which are paid by Medicaid at higher rates, deliver heavier care than do freestanding SNFs, data from a freestanding AIDS-dedicated SNF[1] suggest nursing times per patient day nearly as high as those we found at a hospital-based SNF. The difference between AIDS and non-AIDS care should be larger in freestanding SNFs, where the average patient is a chronically ill older woman receiving minimal nursing care, primarily from allied health personnel.[22] Thus, our comparison of care for PWAs and care for non-AIDS patients in the hospital-based SNF is a conservative test of the differences in nursing care for these two groups. Our small sample size limits the power of the analysis, however, and a more refined analysis of which patients and diagnoses account for care differences will require a study of a larger number of patients from a representative sample of facilities. Future research should focus on subsamples of PWAs in nursing homes, particularly intravenous drug users and ethnic minorities. □

Risk Factors Associated with the Classification of Unspecified and/or Unexplained Causes of Death in an Occupational Cohort

Donna L. Cragle, PhD, and Amie Fetcher, DVM, MPH

ABSTRACT

In a matched case-control study of an occupational cohort in East Tennessee, data from the death certificates of 608 cases and controls were abstracted and analyzed in order to investigate possible risk factors associated with the certification on the death certificate of an ill-defined cause of death. There was a very strong association between the ill-defined classification and the certifier, especially if the certifier was a medical examiner (OR = 10.4, 95% CI: 6.0, 18.0). (*Am J Public Health.* 1992;82:455–457)

Introduction

Results from cohort studies of workers at Department of Energy (DOE) facilities in Oak Ridge, Tenn, indicated unusual increases in the rate of deaths due to unexplained and/or unspecified causes (*International Classification of Diseases,* 8th version, codes 780 to 796).[1,2] The standardized mortality ratio for deaths coded to these disease categories was 3.05 (338 observed vs 110.92 expected). This increase may have reflected actual increases in the incidence of these unexplained causes of death, variations in the quality and accessibility of health care, and/or inaccuracies recorded on death certificates for the underlying cause of death. These inaccuracies most commonly involve problems related to making the distinction between the underlying cause of death, the immediate cause of death, the manner of death, and conditions contributing to death.[3]

The objective of this study was to determine the association between various factors and a recorded ill-defined cause of death.

Methods

Study Population

The cases and controls were chosen from the pooled cohort of all White male DOE Oak Ridge facility workers who worked for more than 30 days between 1943 and 1982 and died between 1945 and 1982. The cohort of workers was com-

posed of more than 70 000 White males, of whom approximately 18 000 were known to have died by the end of 1982.

Six hundred and eight "cases" (individuals who had died of unexplained and/or unspecified causes) were identified, and the same number of controls (individuals who had died of specific causes) were selected. Cases and controls were matched by date of birth (± 2 years), year of death (± 2 years), and facility of employment. Information abstracted from the death certificates of the cases and controls included marital status, state of birth, county/state of residence, county/state of death, place of residence (inside or outside of the city limits), job classification (professional, skilled, or unskilled), location of death (hospital, other institution, home, or other place), type of hospital (rural, urban, teaching, or Veterans Administration [VA]), hospital status (dead on arrival [DOA], emergency room [ER], or inpatient), autopsy examination (yes or no), and certifier (attending physician, medical examiner, coroner, or other).

Data Analysis

Descriptive information about the differences between the cases and controls was determined from frequency distributions for the classification variables. Matched conditional logistic regression analysis using the SAS-PHGLM[4] program was used to analyze associations, control for confounding, and determine odds ratios (ORs) and 95% confidence intervals (CIs) for the various classification variables.

Results

On the basis of the frequency distributions for year of birth, year of death, and age at death, the cases were matched well with the controls. These distributions are presented in Table 1. Data for cases and controls by state of birth, residence, and death were collapsed into two categories, (1) "Tennessee" and (2) "not Tennessee." All the frequency distributions for these single factors were significantly different between cases and controls ($P < .001$).

SAS-PHGLM was used to analyze a full model that included all variables with complete sets of data. The variables in this model were state of death, residence (inside or outside of city limits), place of death, marital status, job classification, length of employment, certifier, and autopsy (yes or no) (Table 2). The OR from this full model for having died in Tennessee and having had an unexplained and/or unspecified cause of death recorded on the death certificate was 3.3 (95% CI = 1.9, 5.6).

A marital status of single (never married, divorced, or widowed) accounted for 30.3% of the cases, compared with 21.5% of the controls. As a factor by itself, this variable was significant ($P < .001$), with an overall OR of 1.7 (95% CI = 1.1, 2.7).

Place of death was one of the most significant variables in the study. The overall OR for dying at home was 2.5 (95% CI = 1.6, 4.0). For those individuals dying in hospitals, the location of the hospital was analyzed with respect to state (Tennessee or not Tennessee), type of hospital (urban, rural, VA, or teaching), and hospital status (DOA, ER, or inpatient). Of all deaths in Tennessee, 59.9% occurred in hospitals; of all out-of-state deaths, 56.1% occurred in hospitals. The type of hospital was not significantly related to the cause of death recorded on the death certificate. However, the status of DOA was significant (OR = 2.7; 95% CI = 1.4, 5.1). Hospital status was unknown for 34.4% of all deaths because many death certificate forms did not request this information.

Autopsies were performed on 9.7% of all workers in the study, and the autopsy rate was significantly different between cases and controls (2.8% and 16.6%, respectively). Overall, the OR associated with no autopsy was 3.1 (95% CI = 1.5, 6.4). Even when an autopsy was performed, the information was not always used to complete the death certificate. Autopsy findings were recorded on the death certificates of only 18.8% of the cases that were autopsied (3/16), compared with 51.5% (51/99) of the controls.

Of all the variables considered, the individual completing the death certificate was the most significant. The overall OR for certification by a medical examiner was 10.4 (95% CI = 6.0, 18.0). Coroners and other certifiers had ORs of 5.7 (95% CI = 3.0, 11.0) and 7.6 (95% CI = 2.0, 27.0), respectively.

Because the cases and controls were matched by year of birth and year of death, age at death could not be considered as an independent factor in the full

model. Instead, the population was divided into two subgroups: (1) "young" (65 years old or less) and (2) "old" (over 65 years old). The full PHGLM model was then used for each of these subgroups. Certification by a medical examiner was a much stronger risk factor for the "old" group (OR = 29.6; 95% CI = 8.0, 110.0) than for the "young" group (OR = 8.6; 95% CI = 4.2, 17.6). The OR for having died at home was also higher for the "old" group (OR = 3.4; 95% CI = 1.4, 8.2) than for the "young" group (OR = 1.8; 95% CI = 1.0, 3.3). Single marital status at the time of death (OR = 2.4; 95% CI = 1.3, 4.3) and not having been autopsied (OR = 3.7; 95% CI = 1.6, 8.6) were both significant risk factors for the "young" group but not the "old" group (Table 1).

Discussion

One of the most surprising findings in this study was the very significant association between the certifier and the classification of cases. For all deaths, the OR for a medical examiner recording an ill-defined cause of death on the certificate was 10.4 (95% CI = 6.0, 18.0). Certification by a coroner or other certifier was also a very significant factor.

The OR of 3.1 (95% CI = 1.5, 6.4) that was associated with not having been autopsied was not surprising. One would have expected that the immediate and underlying causes of death would be determined from a postmortem examination. However, it was surprising that the autopsy findings were not recorded on all death certificates, even as a follow-up report of a pending investigation. The findings were not recorded in 15.0% of all autopsies.

When the study population was divided into "young" (65 years and under) and "old" (over 65 years) subgroups, the risk factors were qualitatively and quantitatively different for each group. The significant factors associated with having had an unexplained and/or unspecified cause of death on the death certificate for the "young" population were (1) death in Tennessee, (2) death at home, (3) single marital status, (4) no autopsy, and (5) a death certificate filled out by a medical examiner, coroner, or other certifier. For the "old" population, significant factors were (1) death in Tennessee, (2) death at home, and (3) certification by a medical examiner, coroner, or other certifier. Single marital status for those dying over 65 years of age was protective, although this was not significant. These findings were unexpected. One would have thought that older, single men might have died alone at home and not have received an autopsy. Under these circumstances, they would have been more likely to have an ill-defined cause of death recorded on the death certificate, especially in light of the high risk associated with certification by a medical examiner for this age group.

The results of this study indicate that the individual completing the death certificate, regardless of qualifications, can have a very important influence on the rate of reporting of certain diseases. In this case, the disease of interest was unexplained and/or unspecified illnesses. Place of death and hospital status were also significant factors associated with certification of an ill-defined cause of death. □

Performance of the Reflotron in Massachusetts' Model System for Blood Cholesterol Screening Program

Stephen Havas, MD, MPH, MS, Robert Bishop, MS, Lauren Koumjian, MSc, Joel Reisman, MS, and Susan Wozenski, MPH, JD

ABSTRACT

The precision, accuracy, and durability of the Reflotron were evaluated by the Massachusetts Model Systems for Blood Cholesterol Screening Program. Screenings were conducted in diverse community settings over 16 months. Fingerstick samples from 10 428 individuals were tested. None of the four analyzers met the 1992 standards for precision, although two met the 1992 standards for accuracy. More than 40% of Reflotron values differed from the reference laboratory values by upwards of 5%. More than 16% of individuals were misclassified in terms of their risk category. All four instruments malfunctioned during the project. (*Am J Public Health.* 1992;82:458–461)

Introduction

At least a dozen portable cholesterol-testing instruments have been designed for use in community and office settings. These instruments have made mass screenings for this risk factor feasible and thus are now in widespread use for this purpose.

To address questions concerning the reliability of this technology, the National Heart, Lung, and Blood Institute supported three projects entitled the Model Systems for Blood Cholesterol Screening Program (MSBCSP).[1] A primary MSBCSP objective was to test the accuracy, precision, and durability of portable analyzers under the usual operating conditions associated with screenings. This article reports findings from Massachusetts' MSBCSP concerning the Reflotron, the lengthiest field evaluation thus far reported.

Methods

From October 1987 to January 1989, the Massachusetts Department of Public Health conducted a blood cholesterol screening project in Chelsea, inner-city Boston, Worcester, and Lowell. The project screened 10 428 individuals in community settings using fingerstick samples analyzed by a Reflotron. Venipuncture blood samples were drawn on 972 participants for comparison.

Most screenings were conducted at work sites although other settings were also used. Two Reflotrons were transported to each site. Three levels of quality control (QC) material were analyzed at the beginning of each screening, after every 10th patient sample, and at the end. Values for QC materials were considered out of range based on Westgard's rules.[2] A reference laboratory at the University of Massachusetts at Lowell, which had met the Centers for Disease Control's Lipid Standardization Program requirements, analyzed the venipuncture serum samples.

Results

For Reflotrons 1, 3, and 4, the weighted average of all values met the current precision goal set by the National Cholesterol Education Program's Laboratory Standardization Panel (LSP) for all three QC levels, but it fell short of the 1992 LSP standards for all levels.[3] For Reflotron 2, the weighted average of the values met the current LSP standards for all QC levels, but the 1992 standards were attained for only two levels (see Table 1).

The bias of the four instruments varied from –3.3% to +3.2%. The differences among the Reflotrons were statistically significant (ANOVA $F = 25.4$, $P < .0001$). All four analyzers met the current LSP standards; only two met the 1992 standards.

As demonstrated in Figure 1, monthly bias on the Reflotron fluctuated considerably. For example, the bias ranged from –6.0% to +2.9% on Reflotron 1. Similar variations were seen on the other Reflotrons.

Figure 2 plots the differences in individual results between the Reflotron and the reference laboratory. One Reflotron 1 reading was 80% higher than the reference laboratory value, a 2.12 mmol/L difference. At the opposite extreme, another Reflotron 1 reading was 57% lower than the reference value, a difference of –3.41 mmol/L. The other plots demonstrate similar discrepancies. Overall, more than 40% of the Reflotron values differed from the

Stephen Havas, Robert Bishop, Lauren Koumjian, and Joel Reisman are all with the Massachusetts Department of Public Health. Susan Wozenski is with the University of Massachusetts at Lowell. This paper was submitted to the journal December 26, 1990, and accepted with revisions June 24, 1991.

venous values by upwards of 5%. The frequency of differences greater than 5% varied from 33% to 47% among the Reflotrons.

The Reflotrons incorrectly classified from 9.2% to 18.5% of individuals regarding their blood cholesterol category. For three Reflotrons, misclassification tended to result in false reassurance; for the other Reflotron, misclassification resulted in false warnings. The differences among the Reflotrons were statistically significant ($\chi^2 = 22.0$, $P < .005$). Overall, 16.3% of individuals were misclassified by the four Reflotrons.

An unanticipated finding was the malfunctioning of the analyzers. Reflotron 2 had to be returned to the manufacturer when its QC results consistently fell out of range. Subsequently, Reflotron 3 had to be returned for similar reasons. On the last two scheduled days for the project, neither Reflotron 1 nor Reflotron 4 analyzed the QC materials within acceptable ranges, resulting in cancellation of the screenings.

TABLE 1—Precision of the Reflotrons, by Percent

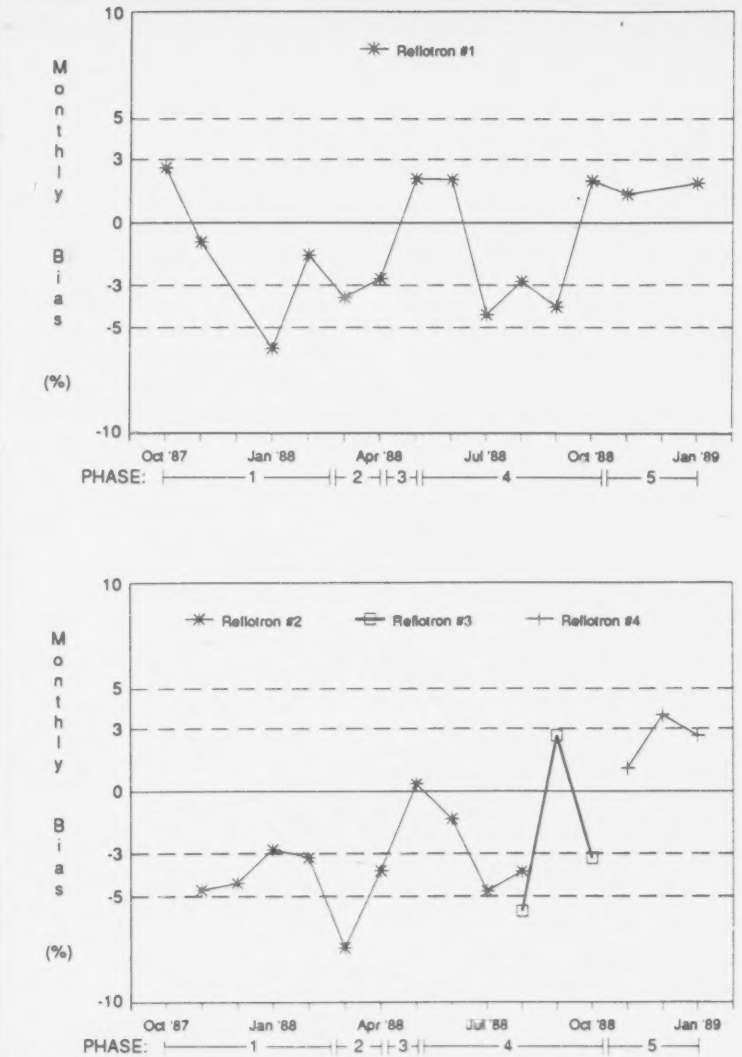

FIGURE 1—Monthly bias plots for the four Reflotrons.

Discussion

The Reflotron has been marketed aggressively for use in community screening programs. The marketing has focused heavily on the instrument's relatively low cost, ease of operation, and accuracy. This strategy has resulted in the widespread use of this instrument in blood cholesterol screenings.

As shown in Table 2, the Reflotron has been studied previously using various settings, sample sizes, and methodologies.[4–21] When placed in the context of these other studies, our results lead to concerns about the widespread usage of the Reflotron. The first concern is that the instrument is not sufficiently precise. Although it does meet current standards, it clearly will not be able to meet the 1992 standards without substantial modifications.

Our second concern is that the Reflotron does not consistently produce accurate results. Accuracy was found to vary greatly over time, both among and within Reflotrons. Our study is the first to show that monthly bias can fluctuate from positive to negative and vice versa for the same Reflotron. This finding is important because it means one cannot simply apply a "correction" factor to screening values based on overall bias.

A disturbing finding is the large individual discrepancies and the frequency of error, which make it difficult to ascertain blood cholesterol levels correctly and to classify individuals appropriately. These inaccuracies occurred despite all four Reflotrons meeting the current LSP standards for precision and accuracy.

Based on our findings and on similar data in two other recent studies,[20,21] it is likely that screening programs will misclassify many people due to the current level of inaccuracy of the Reflotron. This could result in various adverse effects. For example, those with high or borderline high blood cholesterol levels who were falsely reassured may not have the follow-up that current treatment guidelines recommend.[22] On the other hand, those

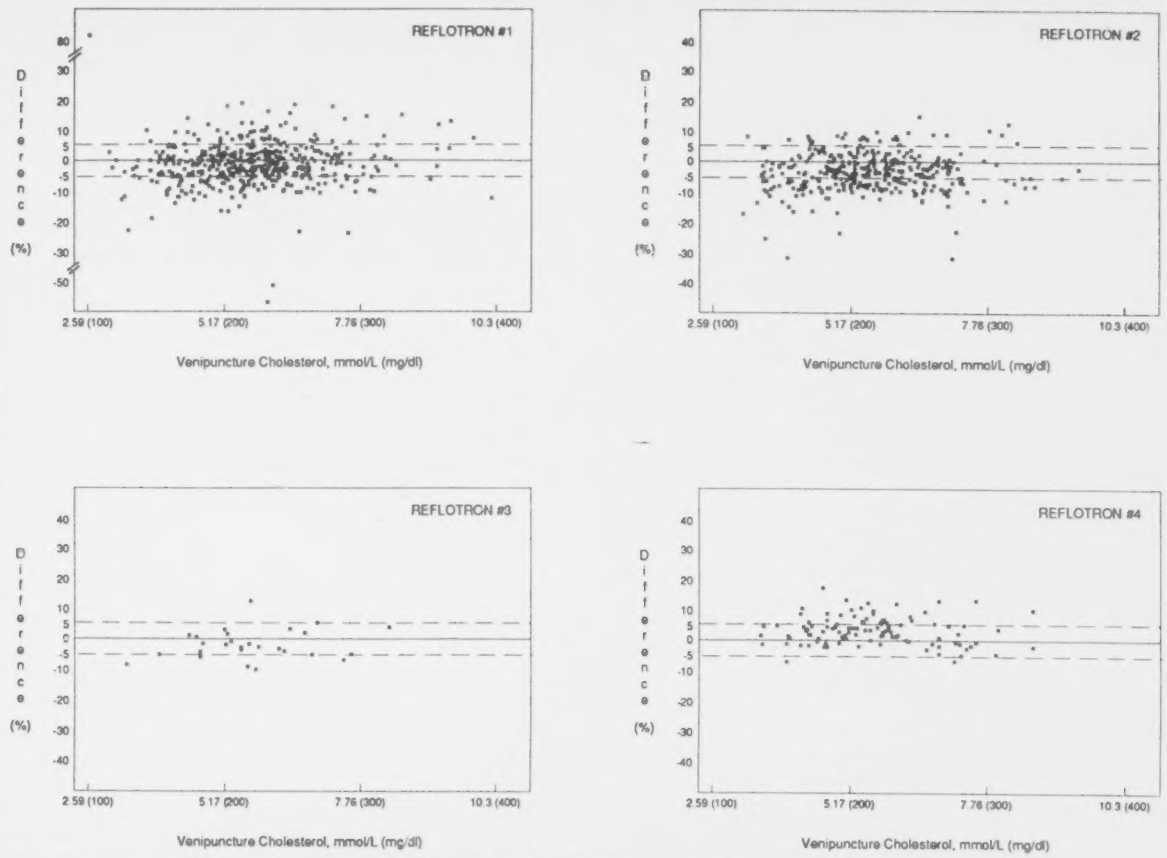

FIGURE 2—Percent difference between results from the four Reflotrons and reference laboratory.

who were falsely warned may visit their physicians unnecessarily, incurring additional tests, costs, and anxiety.

The frequent breakdown of the Reflotrons is also worrisome. For analyzers to be useful to screening programs, they must be precise, accurate, and durable. Our Reflotrons were not sufficiently durable to be considered optimal.

The public's enthusiasm for blood cholesterol screening programs is likely to continue for quite some time. Such programs have the potential to improve awareness and control rates for high blood cholesterol substantially. To provide the quality of blood cholesterol measurements that this important public health problem warrants, however, requires either improvements in the Reflotron or the use of other, more reliable analyzers. □

Acknowledgments

This study was funded by the National Heart, Lung, and Blood Institute grant number RO1HL37832. The authors wish to acknowledge Gene Rogers, PhD (University of Massachusetts at Lowell), for his thoughtful review of this manuscript and the helpful suggestions he provided. The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Factors Associated with AIDS Risk Behaviors among High School Students in an AIDS Epicenter

ABSTRACT

Background. A greater understanding of the determinants of risky behaviors is an essential precursor to the development of successful AIDS prevention programs for adolescents.

Methods. A survey measuring AIDS-related behaviors, beliefs, and knowledge was administered to a sample of 531 10th-grade students residing in an AIDS epicenter.

Results. Of the 56.8% of students reporting past-year involvement in sexual intercourse, 67.3% reported unprotected intercourse with low-risk partners, 1.3% reported unprotected intercourse with high-risk partners, and 6.6% reported a past-year history of a sexually transmitted disease. Students whose friends had intercourse and never or inconsistently used condoms, who personally sanctioned intercourse involvement, who believed that the majority of their peers had intercourse, and who perceived low preventive action self-efficacy, were 5.1, 3.0, 2.1, 3.7, and 2.8 times more likely, respectively, to score in the riskier categories of an AIDS behavior index.

Conclusions. These findings suggest that addressing socioenvironmental influences on risky and preventive behaviors may prove to be the most effective AIDS prevention strategy among adolescents. (*Am J Public Health.* 1992;82:528–532)

Heather J. Walter, MD, MPH, Roger D. Vaughan, MS, Madeline M. Gladis, PhD, Deborah Fish Ragin, PhD, Stephanie Kasen, PhD, and Alwyn T. Cohall, MD

Introduction

Adolescents, particularly those residing in or near one of the nation's acquired immunodeficiency syndrome (AIDS) epicenters, are at increasing risk of acquiring infection with human immunodeficiency virus (HIV), the virus that causes AIDS.[1] Although the total number of reported AIDS cases among 13- to 19-year-olds thus far is small, the caseload in this age group has increased by 40 percent in the past year alone.[1] Moreover, one fifth of all AIDS cases has been reported among 20- to 29-year-olds,[1] many of whom acquired HIV infection as teenagers. Accordingly, the development, implementation, and evaluation of AIDS prevention programs for inner-city adolescents has become a recent public health priority.[2]

A greater understanding of the determinants of risk-related and preventive behaviors in target populations is an important precursor to the development of successful AIDS prevention programs.[3] In the past several decades, a number of theoretical models have been advanced to predict involvement in a variety of preventive actions.[4–6] Recently, constructs derived from several of these models have been applied theoretically and empirically to risky and preventive behaviors specific to AIDS,[7–11] and therefore these models were selected for inclusion in this investigation.

The health belief model[4] posits that individuals who believe that they are personally susceptible to the target disease, that the consequences of having the disease would be severe, and that the benefits of engaging in preventive actions outweigh the barriers are more likely to adopt preventive behaviors than are individuals not holding these beliefs. Social cognitive theory[6] suggests that one's appraisal of one's self-competence (i.e., self-efficacy) pertaining to preventive behaviors generates the self-confidence necessary for the successful performance of these behaviors. Finally, a recently proposed model of reference group–based social influence[11] hypothesizes that behavioral norms (beliefs about how people typically act) and values (beliefs about how people ought to act) interact to generate a normative standard to which individuals aspire to conform, thereby influencing the adoption and maintenance of preventive behaviors.

To investigate the associations between beliefs derived from the seven constructs outlined above (susceptibility, severity, benefits, barriers, self-efficacy, norms, and values) and involvement in AIDS risk and preventive behaviors, a survey was administered in the spring of 1990 to a sample of 10th-grade students residing in an AIDS epicenter. The purpose of the survey was to identify correlates of risky and preventive behaviors that could be targeted for modification or reinforcement, respectively, in preven-

Heather J. Walter, Stephanie Kasen, and Alwyn T. Cohall are with the College of Physicians and Surgeons, Columbia University, New York, NY. Roger D. Vaughan, Madeline M. Gladis, and Deborah Fish Ragin are with the New York State Psychiatric Institute, New York, NY.

tion programs. The survey analyses had four goals: first, to ascertain the prevalence of AIDS risk and preventive behaviors; second, to determine whether these behaviors varied by age, gender, race/ethnicity, school attended, or AIDS-related knowledge; third, to describe the cross-sectional associations of AIDS risk and preventive behaviors with beliefs derived from the constructs identified above; and fourth, to determine whether the observed belief–behavior associations varied according to the demographic and knowledge variables identified above.

Methods

Subjects

Tenth-grade students in 2 of the 14 public academic high schools in a New York city borough were selected as the eligible study population. The two schools were selected on the basis of their willingness to participate in the survey and their racial/ethnic similarity to the entire population of the 14 schools. Passive parental consent was required for students' participation in the survey; the nonconsent rate was 5.5% in one school and 6.5% in the other. The mean age of participants (n = 531) was 16.0 years (SD, 1.0; range, 13 to 21 years); 44.3% of the participants were male. The racial/ethnic distribution of the participants was 59.2% Black, 28.3% Hispanic, and 12.5% other (primarily non-Hispanic Whites); the participants were predominantly from working-class or welfare-recipient families. The demographic distribution of the survey participants was similar to that of the eligible study population.

Measurements

Survey forms were distributed by research staff to all consenting, present 10th-graders enrolled in required general education courses in the spring semester of 1990. Survey completion required one class period; responses to the survey were anonymous.

AIDS-risk behaviors. The students were asked to complete five items regarding past-year involvement in AIDS risk and preventive behaviors, including use of illicit intravenous drugs, involvement in sexual intercourse, number and risk status of sexual partners, and consistency of condom use during sexual intercourse. A high-risk sexual partner was defined as one who was believed by the respondent to have a history of male homosexual intercourse or illicit intravenous drug use. An AIDS behavior index, ranging from lower to higher risk of acquiring infection with HIV, was created from these items according to the epidemiological model of HIV transmission proposed by Hearst and Hulley.[12] Index scores ranged from 0 to 6; the definition of each risk level is presented in Table 1.

Beliefs derived from the health belief model. The students were asked to complete two items pertaining to perceived susceptibility to AIDS and three items pertaining to perceived severity of AIDS; and 15 and 17 items, respectively, constituting additive scales of the perceived benefits of and barriers to engaging in AIDS-preventive behaviors (i.e., sexual abstinence, consistent condom use, sexual monogamy, and knowing the sexual and drug use histories of sex partners). The internal consistency (alpha coefficient) of the benefits scale was 0.81, and that of the barriers scale, 0.77.

Beliefs derived from social cognitive theory. The students were asked to complete 13 items constituting an additive scale of perceived self-efficacy pertaining to the preventive actions identified above. The internal consistency (alpha coefficient) of the scale was 0.80.

Beliefs derived from the model of social influence. The students were asked to complete eight items assessing their beliefs about how many of their four closest friends and what proportion of the students in their grade were involved in the past year in the preventive behaviors identified above (i.e., beliefs about norms). They were also asked to complete four items assessing whether they personally believed that people their age should be involved in these behaviors (i.e., beliefs about values).

AIDS-related knowledge. The students were asked to complete 12 items pertaining to the transmission and prevention of HIV infection. These items were selected on the basis of their measurement characteristics from an original 72-item scale; the internal consistency (alpha coefficient) of the original scale was 0.82.

Statistical Analysis

The analytic strategy comprised four steps. First, descriptive statistics were calculated to provide prevalence data for the investigated behaviors and beliefs, and bivariate relations between the behaviors and beliefs were assessed by computing odds ratios (ORs) and associated 95% confidence intervals (CIs). Second, multiple logistic regression was employed to assess differences in the distribution of AIDS behavior index scores across the five demographic and knowledge variables. Logistic rather than linear regression was employed because of the multinomial nature of the distribution of the AIDS behavior index scores. Accordingly, the AIDS behavior index scores were dichotomized to reflect lower versus higher risk. Third, multiple logistic regression again was used to assess the unique associations between beliefs derived from the seven investigated theoretical constructs and the AIDS behavior index scores. Finally, interaction variables, created by multiplying each demographic term or terms by the significantly associated beliefs, were added to the regression model to assess interaction effects.

TABLE 1—Proportions (in percent) of Students in each Category of the AIDS Behavior Index (n = 531)

Category[a]	Males	Females
0	38.4	46.7
1	8.9	10.6
2	8.2	1.6
3	13.7	30.1
4	26.0	6.5
5	0.0	0.0
6	4.8	4.5

[a]Category 0 = sexual abstinence and no illicit intravenous (IV) drug use.
Category 1 = sexual intercourse consistently using a condom with one low-risk partner and no illicit IV drug use.
Category 2 = sexual intercourse consistently using a condom with two or more low-risk partners and no illicit IV drug use.
Category 3 = sexual intercourse with one low-risk partner without or inconsistently using a condom and no illicit IV drug use.
Category 4 = sexual intercourse with two or more low-risk partners without or inconsistently using a condom and no illicit IV drug use.
Category 5 = sexual intercourse consistently using a condom with one or more high-risk partners and no illicit IV drug use.
Category 6 = sexual intercourse with one or more high-risk partners without or inconsistently using a condom, or illicit IV drug use, or history of a sexually transmitted disease.

Results

AIDS-Risk and Preventive Behaviors

Nearly two thirds (64.6%: 76.7% of males and 55.6% of females) of this sample of 10th-grade students reported ever having had sexual intercourse. The modal age of initiation of intercourse was 11 years for males and 15 years for females. Three fifths (59.3%: 59.5% of males and 59.2% of

TABLE 2—Multivariate Odds Ratios (ORs)[a] and 95% Confidence Intervals (CIs) for Past-Year Higher AIDS Risk,[b] Given Modeled Beliefs (n = 531)

Modeled Beliefs	OR (95% CI)
Friends had intercourse in past year (Two to four vs none or one)	5.1 (2.5,10.7)
Friends never or inconsistently used condoms in past year (Two to four vs none or one)	3.0 (1.8,4.9)
People my age should have intercourse (Should vs should not)[c]	2.1 (1.3,3.5)
Peers had intercourse in past year (≥ 1/2 vs < 1/2)	3.7 (1.1,12.3)
Preventive action self-efficacy (Bottom vs top tertile)	2.8 (2.1,3.9)

[a]Odds ratios are adjusted for age, gender, race/ethnicity, school, and AIDS-related knowledge.
[b]Higher AIDS risk includes categories 3–6 (see Table 1).
[c]Dichotomized responses to a 7-point Likert scale (should = 1 to 3; should not = 4 to 7)

TABLE 3—Proportions of Students (in percent) Endorsing "Not at all sure," "A little sure," and "Somewhat sure" Responses to Self-Efficacy Items (n = 531)

Self-Efficacy Items	Males	Females
Refuse intercourse with longtime date	65.6	67.5
Refuse intercourse with partner you want to fall in love with you	67.6	60.4
Refuse intercourse if "high" or "drunk"	67.5	46.8
Refuse intercourse if partner's sex and drug histories unknown	64.2	38.8
Refuse intercourse if condom not used	69.2	31.1
Purchase condoms	36.9	54.4
Use condoms when "high" or "drunk"	56.2	38.0
Use condoms correctly	44.1	31.1
Use condoms consistently	43.2	29.5
Remain sexually monogamous	61.8	8.0
Ask sex partner about drug use history	40.0	22.7
Ask that condom be used during intercourse	36.1	16.0
Ask sex partner about sex history	37.5	14.9

females) reported ever having used (or having had their partner use) a condom during intercourse.

Table 1 presents the proportions of students reporting past-year involvement in each category of AIDS-related behaviors. No students reported use of illicit intravenous drugs; less than half reported sexual abstinence. Only one fifth of sexually active students reported protected intercourse with one low-risk partner.

Belief–Behavior Correlations

Significant bivariate associations were observed between beliefs derived from all seven investigated theoretical constructs (i.e., susceptibility, severity, benefits, barriers, self-efficacy, norms, and values) and the AIDS risk behavior scores. However, in a multivariate analysis in which beliefs derived from all seven constructs were entered into the model along with age, gender, race/ethnicity, school attended, and AIDS-related knowledge, beliefs derived from only three (i.e., norms, values, and self-efficacy) of the seven constructs were significantly associated with involvement in higher-risk behaviors (Table 2). In the presence of beliefs derived from these three constructs, beliefs derived from the four health belief model constructs (i.e., perceived susceptibility to and severity of AIDS, and perceived benefits of and barriers to engaging in preventive actions) were not significantly associated with higher-risk behaviors.

The analyses revealed a significant main effect of age on AIDS behavior index scores: older students were slightly more likely to be in the higher categories of risk than were younger students (OR = 1.2 per year; 95% CI, 1.1 to 2.1). The analyses failed to provide any evidence of significant main effects of gender, race/ethnicity, school attended, or AIDS-related knowledge on the index scores, nor was there evidence of interaction between any of these variables and the belief–behavior associations.

The great majority of the students believed that half or more of their peers and friends had had sexual intercourse in the past year; half of the students believed that half or more of their friends had never or inconsistently used condoms in the past year. Three fifths of the males, but only one quarter of the females, believed that people their age should have intercourse. Substantial proportions of the students (in general, more males than females) were not sure that they could perform certain behaviors essential for effective AIDS prevention (Table 3).

Discussion

Our principal finding is that a substantial proportion of a sample of 10th-grade students residing in an AIDS epicenter reported involvement in behaviors that place them at risk for acquiring infection with HIV. Beliefs derived from three theoretical constructs (i.e., norms, values, and self-efficacy) were cross-sectionally associated with riskier behaviors. In the presence of beliefs derived from these three constructs, beliefs derived from health belief model constructs were not significantly associated with higher AIDS risk.

Before we consider the implications of these results, some methodological issues should be addressed. First, because of the self-report nature of the survey, the veracity of students' responses may be questioned. However, responses to the survey were anonymous to maximize accurate self-disclosure. In addition, there was high agreement (above 98%) of responses to similarly worded items assessing the same behavioral domains that were dispersed throughout the survey. The validity of responses also is strengthened by the similarity of the behavior prevalence rates reported in this study to those reported in other studies.[13–18] Finally, there is evidence suggesting that questionnaire data are as accurate as interview data in assessing sexual-behavior prevalence rates among groups of subjects.[19]

Second, although the high survey participation rates obtained in this study suggest that the findings may be generalizable to similar populations of students, the findings may not be applicable to students attending schools unwilling to participate in such surveys, to students with a different demographic profile, or to teen-

agers who are habitually absent or have withdrawn from school.

A number of recent studies[13–18] conducted among various populations of adolescents have suggested that substantial proportions of teenagers and young adults engage in behaviors that increase their risk for acquiring infection with HIV. The most common behavioral profile among sexually active adolescents in this sample was a teenager who had unprotected sexual intercourse with partners believed to be at low risk for carrying HIV. Because in the absence of HIV antibody testing one cannot be certain that one's partner indeed is uninfected,[20] and because seropositivity rates in AIDS epicenters are estimated to be high,[21] this behavioral profile (which is applicable to over two thirds of the sexually active students in this sample) conveys nontrivial risk to these teenagers. Of particular concern because of their greatly increased risk of HIV infection[12] are the 1.3% of the sexually active students in this sample who reported unprotected intercourse with high-risk partners, and the 6.6% who reported a history of sexually transmitted disease (similar percentages also have been reported elsewhere).[13–18]

Although a number of studies have documented the prevalence of AIDS risk behaviors among adolescents, fewer have investigated theoretically or empirically suggested determinants of these behaviors. The findings of two studies recently conducted among teenagers have been informative in this regard. Hingson et al.[8] showed that beliefs about the benefits and barriers of condom use and beliefs about susceptibility to getting AIDS were associated cross-sectionally with condom use, as is predicted by the health belief model. Kasen et al.[10] demonstrated that intercourse refusal and condom use self-efficacy were correlated with involvement in sexual intercourse and condom use among adolescents, net of the influence of beliefs derived from health belief model constructs, as is predicted by social cognitive theory.

The findings from this study demonstrate that although bivariate associations between beliefs derived from health belief model constructs and AIDS risk behaviors were observed, these associations were attenuated in the presence of certain socioenvironmental factors (i.e., beliefs about norms, values, and self-efficacy). The results are similar to those reported from a number of studies examining factors influencing drug use among teenagers,[22–24] and suggest that individual/cognitive interventions (e.g., those based upon the health belief model) emphasizing the disease-related knowledge and beliefs of individuals as they exist apart from the social world may have only small effects on teenagers' motivations to initiate preventive actions. Instead, a more productive strategy may be to address salient socioenvironmental influences on preventive behaviors. For example, the data from this study suggest that teenagers could be helped to clarify their personal values relating to involvement in preventive actions, and an understanding of the effects of outside influences (e.g., peer pressure) on those values could be facilitated. Adolescents' misconceptions about the prevalence of risky and preventive behaviors among their peers could be corrected. Preventive action self-efficacy could be enhanced by empowering youths with the skills necessary to successfully perform risk-reducing behaviors. Skills in which teenagers may be particularly deficient include questioning sexual partners about sex and drug-use histories, using condoms correctly and consistently, and refusing offers to engage in sexual intercourse in certain high-pressure social situations.

In summary, teenagers (particularly those residing in or near AIDS endemic areas) are at risk for acquiring infection with HIV. Because certain socioenvironmental factors (i.e., beliefs about norms, values, and self-efficacy) may strongly influence involvement in AIDS risk behaviors, further elucidation of the social influence process among adolescents should become a prevention research priority. For the present, it may prove to be beneficial for practitioners to reinforce values incompatible with involvement in AIDS risk behaviors, correct misconceptions about the normative status of such behaviors, and teach skills enabling effective, sustained preventive action. □

Deadline: May 1, 1992

AIDS Education for Drug Abusers: Evaluation of Short-term Effectiveness

Jane McCusker, MD, DrPH, Anne M. Stoddard, ScD, Jane G. Zapka, ScD, Charles S. Morrison, PhD, Martha Zorn, MS, and Benjamin F. Lewis, EdD

ABSTRACT

Background. Interventions are needed to assist drug abusers in reducing risky drug and sexual behavior.

Methods. A randomized controlled trial compared three small-group AIDS educational interventions among 567 clients of a 21-day inpatient drug detoxification program: a two-session informational intervention, given either during the first (early) or second (late) week of treatment; and a six-session enhanced intervention. Changes in knowledge, attitudes, and psychomotor skills were assessed before and after each intervention, and behavioral outcomes were assessed at follow-up 10 to 18 weeks after admission.

Results. Immediately after the interventions, enhanced group members reported significantly greater self-efficacy to talk themselves out of AIDS-risky behavior; other knowledge and attitude scales did not differ by intervention. At follow-up, significant reductions in risky drug use were reported by all groups. Enhanced group members reported significantly greater reduction in injection frequency than did late informational subjects.

Conclusions. No beneficial effect was detected of delaying AIDS education for clients entering detoxification. At this early stage of follow-up, there is only weak evidence that an enhanced intervention improved outcomes. (*Am J Public Health.* 1992;82:533–540)

Introduction

Drug users, particularly intravenous drug users, are a critical target group for acquired immunodeficiency syndrome (AIDS) educational interventions.[1] In this study we focused on drug users admitted to a short-term, inpatient drug detoxification and rehabilitation program in central Massachusetts, with the expectation that this temporarily captive population might be more receptive to educational programs than one concurrently using drugs. Because the program is short, usually not more than 21 days, and most clients return to drug use following discharge, this seemed an important opportunity for an intervention that might have a "ripple effect" on clients' peers in the community in addition to the anticipated risk reduction among clients who participated in the program.

The objectives of the study were to compare the effects of two AIDS risk reduction interventions, informational and enhanced. The *informational* strategy was based on "standard" AIDS education programs commonly provided in treatment settings, which primarily impart information. In two 1-hour group sessions in which a specially designed video, lectures, homework, and class discussion were used, the subjects were provided with basic information about human immunodeficiency virus (HIV) transmission, prevention, symptoms, and testing. The subjects watched demonstrations of condom use and cleaning of drug paraphernalia with a real needle and syringe, but did not practice themselves.

Although the theoretical basis for the informational intervention included concepts from the Health Belief Model[2] and the theory of reasoned action,[3] the *enhanced* intervention emphasized this material more heavily. The enhanced intervention was based primarily on social cognitive theory[4] and relapse prevention theory.[5,6] A broader interpretation of relapse was used, which included not only relapse to drug use, but relapse to HIV-risky drug-use and sexual behaviors.

The enhanced intervention consisted of six 1-hour group sessions, followed by a 30-minute individual health education consultation, and focused on personal susceptibility, situational analysis, and skill building. Although the essential information about HIV and AIDS (prevention, transmission, etc.) was provided in the same manner as in the informational interventions, the enhanced classes focused on putting the knowledge into practice as well as on a more thorough discussion and practice of situations and skills. A variety of methods were used, including in-depth class discussions, additional homework, tension release exercises, role-playing, trigger tapes, peer feedback, and hands-on needle cleaning and condom exercises. The experiential learning was intended to enhance the subjects' self-efficacy regarding their ability to use skills that would assist them in initiating and maintaining AIDS harm reduction behaviors.

The study was designed to test hypotheses regarding the relative effectiveness of the informational versus the enhanced intervention. Because the two

interventions contained similar information, we hypothesized that they would be equally effective in achieving improved knowledge, but that the enhanced intervention would be more effective in changing attitudes, beliefs, skills, and behavior.

A second set of hypotheses was related to the timing of the informational intervention. We felt that the clients being detoxified on methadone might be less receptive to the intervention during the first week of detoxification, owing to the effect of higher doses of methadone. We therefore hypothesized that the informational intervention given early in the detoxification program (days 5–8) would be less effective, and the same intervention given at a later stage (days 10–15) would be more effective, because most clients would be at lower doses of methadone (5 or 10 mg/day) or completely drug-free. Because the enhanced program required a longer period of time, it was not feasible to compare an early and a late time of administration of the enhanced intervention. We therefore limited the intervention groups to three: early informational, late informational, and enhanced.

Methods

Baseline Characteristics of Study Sample

The majority of the subjects were male (67%), white (81%), high school graduates (70%), and gave English as their first language (92%). Of those whose first language was not English, 84% gave Spanish as their first language. The majority (80%) had had previous drug abuse treatment episodes. Prior HIV testing results and risk period behaviors are shown in Table 2.

The following baseline characteristics of subjects did not differ significantly at the $P<.01$ significance level by intervention group: gender; prior HIV antibody testing and result; levels of the summary drug-use and sexual risk behaviors (the latter stratified by gender); knowledge, attitudes and beliefs, and psychomotor skills.

Design

A blocked randomization design with pretest and multiple posttests was used. The interventions were allocated by date of admission, with all clients admitted during a specified period given the same intervention, regardless of their participation in the research. Each intervention admission period was planned to be 6 1/2 weeks long and the interventions were randomly ordered in blocks of three. Thus, each intervention would be given four times over the course of the study. In this way any seasonal fluctuation in admissions or secular trends in knowledge or behavior would be spread over all interventions. Furthermore, this length of admission period was intended to reduce the contamination between interventions by minimizing the number of transition periods. Small adjustments were made in the randomization schedule to balance the numbers of study subjects in the three study groups.

Table 1 shows the schedule of research contacts with subjects. Clients were approached for consent to participate on the first or second day of the program. The timing of the interviews during the treatment program was designed to assess subjects at baseline (T0), after the early informational but before the late informational intervention (T1), and after completion of both the late informational and enhanced interventions (T2). Follow-up interviews (T3) took place between 10 to 18 weeks after admission. Longer-term follow-up was carried out but is not reported here.

A nonintervention control group was not included. The purpose of this study was to evaluate the incremental effects of the enhanced over the more standard informational intervention, inasmuch as we believe that most drug treatment programs offer some basic form of AIDS education to their clients. In addition, we considered it unethical not to provide at least the in-

formational intervention to all subjects, in view of the severity of HIV disease and the highly susceptible client population. However, because the late informational group received no intervention before the T1 interview, they provided a control for the evaluation of the immediate effects of the early informational intervention.

The subjects received counseling regarding HIV antibody testing during their first week, and were given the option of HIV antibody testing at any subsequent point during their stay. If testing occurred, the results were released, with posttest counseling, after completion of the T2 interview, to avoid contamination of the intervention effect.

Outcomes

Primary study outcomes included selected attitudes and beliefs, knowledge, psychomotor skills, and drug-use and sexual behaviors. Selected secondary outcomes included program retention, HIV antibody testing, and initiation of longer-term drug abuse treatment following exit.

Four knowledge scales assessed knowledge of methods whereby HIV is transmitted, methods for prevention of transmission, ways to prevent progression to AIDS, and understanding of the HIV antibody test. Attitude and belief items or scales assessed perceived susceptibility to AIDS, benefits of risk reduction, attitudes toward slips in drug-use and sexual risk behaviors, and self-efficacy for eight relevant risk reduction behaviors. Psychomotor skill scales assessed the client's demonstration of correct methods for cleaning injection equipment with bleach and using a condom. (See Appendix for a description of variables).

The reporting period for drug-use and sexual behaviors at baseline and follow-up was the "risk period," defined as the most recent free-living period of at least 1 week and not more than 3 months.[7] Drug-use behaviors reported included type of drugs used and route of administration. Drug injectors were asked about two forms of sharing of injection equipment: borrowing of injection equipment previously used by others, and lending of injection equipment to others after first using it. Specific information requested included frequency of injection, borrowing, and lending of injection equipment, and cleaning of borrowed injection equipment with bleach before use; and numbers of persons who had previously used borrowed injection equipment ("sharing partners"). A composite drug-use risk variable was constructed from reported injection, borrowing, and bleach use. Sexual behaviors reported included numbers of sexual partners of the same and opposite sex and use of condoms during vaginal or anal sex; a composite sexual risk variable was constructed from these responses (Table 2).

TABLE 1—Schedule and Content of Research Contacts with Study Subjects

Time from Admission	Nature of Contact
1–2 days	Study introduction and informed consent
2–5 days	Baseline (T0) interview; baseline knowledge, attitudes, skills
7–10 days	Time 1 (T1) interview: repeat knowledge and attitudes: baseline behavior
11–15 days	Time 2 (T2) interview: repeat knowledge, attitudes, skills
10–18 weeks	Follow-up (T3) interview: follow-up behavior, attitudes, skills

Note. T1 interview took place after the early informational and before the late informational intervention, the T2 interview took place after all interventions; the T3 interview took place after the subject's discharge from the program.

Statistical Methods

The primary hypothesis-testing analyses followed the "intention to treat" principle, and included all subjects allocated to a given intervention, whether or not they actually received it as planned. Each analysis was computed using subjects who completed the relevant pre- and posttests (T0–T2) within 1 day of the protocol windows.

Each analysis compared the change in the outcome from pretest to posttest across study groups. For continuous and interval outcome measures, the difference in outcome between two time points was computed and study-group mean differences were compared by Student's t test or the one-way analysis of variance.[8] For ordinal categorical measures, changes in outcome were compared by a method based on the cumulative logit.[9]

Owing to the large number of hypothesis tests involved, statistical significance was determined by a P value of less than .01. All analyses were computed with the personal computer version of SAS.[10]

Enrollment and Attrition

All clients admitted to the detoxification program from July 25, 1988, to February 24, 1990, were eligible for study enrollment, unless they had enrolled or had received any of the study interventions during a prior admission.

During the recruitment period there were 961 admissions to the detoxification program. Of these admissions, 116 (12%) occurred during periods of nonenrollment due to understaffing, either of interviewers or the health educator, and 178 (18%) were readmissions of persons previously admitted during either the study period or the pretest of the study protocol, and who were therefore ineligible for study enrollment. Out of the 667 first admissions during enrollment periods, 4 clients were unable to complete the interviews because of language barriers, 13 left the program before their participation in the study could be requested, and 32 left against staff advice or were discharged before beginning the study protocol. Of the remaining 618 persons, 51 (8.3%) refused to participate, leaving 567 subjects in the study sample.

The following numbers of subjects completed scheduled in-house interviews within 1 day of the protocol window period: T0—557 (98%); T1—479 (84%); T2—415 (73%); and 335 (59%) completed the T3 follow-up interview within the scheduled window period of 18 weeks from admission. Behavioral outcomes were assessed among those 301 subjects who had completed the T1 interview within 1 day of the protocol window period and who also completed a T3 interview. Completers and noncompleters of any given interview did not differ by age, gender, race, education, intervention group, detoxification drug, or baseline level of the outcome variables. Only language was an important predictor of completion. Subjects whose first language was not English had significantly lower interview completion rates.

Results

Participation in Intervention, HIV Testing, and Further Treatment

The length of stay in the detoxification program varied from 1 to 30 days, with a median of 18 days, and was not

TABLE 3—Mean Levels (and Standard Deviation) of Knowledge, Attitudes, and Skills at T0 and T2 Interviews

	Scale Range	T0	T2	No.
Knowledge				
Transmission methods	0–10	5.11 (1.96)	6.97 (2.15)	409
Transmission prevention	0–8	5.14 (1.17)	5.52 (1.29)	409
Prevention of progression	0–6	1.60 (1.18)	2.24 (1.01)	409

Condom use	0–1	0.32 (0.47)	0.88 (0.32)	359

Note. T0 was the baseline interview; the T2 interview took place after all interventions.

associated with intervention. Most subjects (78%) were detoxified with methadone.

Altogether, 411 subjects (72%) attended all group sessions; complete attendance was lower for the enhanced group (68%) than for either informational group (74% and 75%), owing to the larger number of sessions in the enhanced intervention.

Overall, 48% of the subjects elected to be tested for HIV antibody while in treatment; 10% of these tested positive. There was a weak association of intervention with testing: 48% and 54% of the early and late informational groups, respectively, were tested, compared with 42% of the enhanced group ($P = .06$).

Of the 331 subjects who gave information on further treatment following exit from the program, 98 (30%) entered residential drug-free programs and 44 (13%) entered other drug abuse treatment programs; these proportions did not differ by intervention group.

Hypothesis Testing

We tested hypotheses related to intervention type and timing, with the latter hypotheses restricted to comparisons of the early versus late informational interventions among subjects detoxified on methadone. To simplify the presentation of results, we have not stratified by detoxification drug. These analyses (available on request) did not change our overall conclusions.

Immediate effects of interventions. At baseline, the subjects displayed moderate levels of knowledge, perceived susceptibility, and skills, but relatively high levels of other attitudes, particularly self-efficacy (Table 3). At the T1 interview, among subjects detoxified on methadone, the early informational group showed greater changes in 12 of the 16 knowledge and attitude items than did the late informational group; however, only knowledge of HIV transmission was statistically significant (data not shown). Members of both groups increased significantly in their knowledge of the test for HIV antibody and in their belief in their ability to recover from a failure to use bleach consistently. The subjects in the early informational group decreased significantly in their perceived susceptibility to AIDS and increased significantly in their knowledge of HIV transmission, knowledge of prevention of HIV infection, belief in the benefits of behavior change, self-efficacy to clean needles with bleach, and self-efficacy to use condoms.

By the T2 interview, the subjects in all intervention groups had increased significantly on almost all knowledge scales, but the differences between groups were not statistically significant (Table 4). There were no significant between-group differences in improvement in attitudes except in self-efficacy to talk oneself out of risky behavior (self-talk). On this item, the subjects in the enhanced group improved more than did subjects in the other two groups. All three groups showed increases in their belief in the benefits of behavior change, in their ability to recover from failure to use bleach consistently, in their self-efficacy to avoid using drugs, and in both their needle-cleaning and condom-use skills. Perceived susceptibility decreased in all three groups, but the change was statistically significant only for the early informational and enhanced groups.

Behavioral effects of interventions. At follow-up, there was a substantial reduction in risky drug-use behavior (Table 5). Only 44% of those interviewed reported drug injection, compared with 77% at baseline. A higher percentage of participants also reported abstinence from vaginal or anal sexual contact at follow-up (33%) than at baseline (19%).

The analysis based on cumulative logits gives an odds ratio for a "safer" behavior category at follow-up relative to baseline for each intervention group (Table 6). For example, subjects in the early informational group were 4.7 times more likely to report a lower frequency of injection at follow-up than at baseline. For most of the behaviors, all groups reported safer behaviors at follow-up than at baseline (odds ratios all greater than unity), with relatively greater behavior changes for frequency of injection and the composite drug-use variable. Less marked changes were found for frequency of borrowing and bleaching and for sexual behavior, and some of the confidence intervals included unity. However, except for frequency of injection, there were no significant differences in changes in behavior between the intervention groups. The odds ratio for the enhanced group is significantly greater than that for the late informational group, but not significantly greater than that for the early informational group.

Secondary Analyses

We repeated the analyses described above, limiting the sample to those subjects who had completed the intervention sessions to which they had been allocated as well as completing the T0 and T2 interviews within 1 day of the protocol windows (n = 339). We obtained essentially the same results as in the primary analyses by "intention to treat."

Because of the weak effect of the intervention on the decision to be HIV-antibody tested, we repeated the analyses of behavior change, using the composite drug-use and sexual behavior variables, with stratification by decision to be tested. Again, the results concerning association between intervention and behavior change remained unchanged, although the odds ratios were closer to unity. In all groups, those who were tested made slightly greater changes in their risky drug behavior than did those not tested, although the difference was not statistically significant. There remained no significant change in risky sexual behavior for any intervention when we stratified by testing.

Discussion

The results of this study show substantial improvement in AIDS knowledge and skills and reductions in risky behavior in the study subjects (achieved primarily through high rates of abstinence from injection and increased celibacy). The comparison of the early and late informational groups at T1 was a controlled evaluation of the informational intervention, and demonstrated changes in knowledge and attitudes attributable to the intervention, although only knowledge of HIV transmission achieved statistical significance. Thus, we conclude that the informational intervention was moderately effective.

Our hypotheses regarding the timing of the informational intervention were not confirmed; the early informational intervention appeared to be at least as effective as the late informational intervention. The "drugged" state of subjects during the earlier stages of methadone detoxification apparently did not compromise their ability to learn from the intervention, as shown by their significant gains in knowledge from T0 to T1. Clinical observations suggested that the period immediately following withdrawal from methadone, which usually occurred during the second week of the program and coincided with the late informational intervention, was particularly stressful for many subjects and may have compromised the effectiveness of this intervention.

The relative effectiveness of the enhanced intervention versus the informational interventions was disappointing. Immediately after the interventions, enhanced-group members reported significantly greater self-efficacy to talk oneself out of AIDS-risky behavior; other attitude items and scales did not differ by group. At follow-up, the enhanced group had made greater reductions in the frequency of injection, but other measures of risky drug-use behavior, including safer injection practices among those who continued to inject, showed no differential effect by intervention. Possibly, injection frequency is reported more reliably than needle sharing and cleaning behavior. Longer-term follow-up is needed to assess outcomes more completely; preliminary analyses of follow-up after 6 months indicate a stronger effect of the enhanced intervention in reducing relapse to injection.[11]

A number of factors may have contributed to a dilution of the treatment effect. Drug users who enter drug abuse treatment are a subpopulation that differs by factors such as education and race from other subpopulations of drug users.[7] Their motivation to change their behavior may have overwhelmed the potential to achieve differences between the interven-

tions. In addition, other components of the detoxification and rehabilitation program, including pre- and posttest counseling, and the extensive data collection for the research may have contributed to a multiple treatment effect.[12]

There was an ongoing process evaluation component to the evaluation plan. It proved very difficult to monitor how often and with what intensity AIDS issues were discussed in individual or other group therapy sessions, and to assess the impact these encounters may have had. Staff were aware of what intervention was going on at a particular time, and may have consciously or unconsciously provided individual AIDS counseling (compensatory equalization of treatment).[13]

Additional influences outside the program undoubtedly affected behavioral outcomes at follow-up. Knowledge of AIDS and methods of risk reduction have affected risky behaviors. In the Worcester, Mass, area, coordinated efforts to educate intravenous drug users about HIV and to distribute bleach have resulted in significant increases in bleach use.[14] There has also been a significant secular decline in sharing reported by intravenous drug users entering drug abuse treatment.[14] In view of all these changes, the effects of the interventions may have been diluted considerably, and "booster" sessions may be required to maintain any initial effect.

Attrition bias due to differential loss to follow-up in the three intervention groups may have affected the results. However, attrition rates did not differ by intervention group, and except for language, our baseline measurements showed no differences between those followed and not followed. Our attrition rate, 41%, is not surprising, given the difficulties in following drug abusers.[15] Additionally, the wide geographic distribution of residences (less than one third of the clients lived in the city where the treatment program was located) and the fact that the follow-up period of 10 to 18 weeks was deliberately truncated contributed to attrition.

Potential information bias must be acknowledged. The measurement of attitudinal outcomes can be problematic in the evaluation of interventions that aim to change perceptions due to "response shift" bias.[16] Thus, subjects in the enhanced intervention may actually have rated their self-efficacy somewhat lower after the intervention because they had gained a more realistic perspective on the difficulty of carrying out the behaviors.

The finding of decreased perceived susceptibility in all intervention groups was initially viewed as counterintuitive, given the volume of documented studies about the role of education in increasing perceived susceptibility.[17] Participation in the educational intervention may have provided subjects with a more realistic assessment of risk, with a concomitant decrease in perceived susceptibility to AIDS. For example, at baseline there was a tendency for participants to overestimate the actual HIV seroprevalence among intravenous drug users in Massachusetts; estimates were more accurate at posttest.

The educational and policy implications of the study are limited at this early stage of follow-up. However, the finding of no substantial differences in outcome between the early and late informational interventions indicates that there is no benefit to delaying AIDS education, particularly because the longer the delay, the more clients are likely to have left the program prematurely. Evaluations of other "enhanced" models of AIDS education for drug users reported to date have also yielded disappointing results.[18,19] Thus, at this point, research does not support the widespread substitution of enhanced models of AIDS education for drug users in place of simpler, informational models.[20] □

Acknowledgments

This research was supported by grant R01 DA04508 from the National Institute on Drug Abuse.

A preliminary version of this paper was presented at the 118th Annual Meeting of the American Public Health Association, New York, NY, September 30–October 4, 1990.

The authors are indebted to the staff and clients of Spectrum Addiction Services, Inc, for their cooperation with this project.

APPENDIX—Description of Scaled and Individual Item Variables

Knowledge

Transmission scale

Ranging from 0 to 10, scored from an open-ended question, this scale measures a subject's ability to name the most important ways that HIV is transmitted: via sharing needles without use of bleach, unprotected vaginal and oral sex, and prenatal transmissions.

Prevention of transmission scale

Ranging from 0 to 8, scored from an open-ended question, this scale measures subject's ability to identify methods to prevent HIV, including: not sharing injection equipment, using bleach, using condoms, and limiting sex partners to one.*

Prevention of progression scale

Ranging from 0 to 6, scored from an open-ended question, this scale measures subject's ability to identify ways that a person infected with HIV stay as healthy as possible, including eating well, reducing stress, exercising, getting enough sleep/rest, not using drugs, and avoiding reinfection through not engaging in unsafe sex or unsafe drug use.*

Test knowledge scale

Ranging from 0 to 6, scored from correct response to 5 Yes/No items:
(1) If a person has a positive result on the AIDS antibody test, does it mean that he or she has been infected with the AIDS virus?
(b) Does it mean the person has AIDS?
(c) Does it mean the person will definitely get AIDS sometime in the future?
(d) Does it mean the person can pass the infection on to someone else?
(e) After a person has been infected with the AIDS virus, how soon will he or she usually become positive on the antibody test (right away, within 1 to 3 weeks, within 1–3 months, more than 3 months, never).

Attitudes and Beliefs**

Susceptibility scale

Perceived susceptibility to AIDS measured by 2 items.
Responses: 1 (strongly agree) to 4 (strongly disagree).
Range: 2 to 8. Cronbach's alpha: 0.70.
(a) Your chances of getting AIDS are quite small.
(b) You are quite likely to get AIDS in the next 5 years.

Benefits scale

Perceived benefits of AIDS-related behavior or change measured by 4 items.
Response: 1 (strongly agree) to 4 (strongly disagree).
Range: 4 to 16. Cronbach's alpha: 0.55.
(a) Using a condom during sex would give you peace of mind.
(b) Doing things to protect yourself and others from AIDS would give you a lot more confidence in yourself.
(c) Each time a person refuses to share works, it gets easier the next time.
(d) Each time a person uses a condom during sex, it gets easier to do so again.

Sex slips recovery—single item

Response: 1 (strongly agree) to 4 (strongly disagree).
(a) If a person promises himself or herself to always have "safe sex" and then "slips" once, he or she can still get in control and do better next time.

Bleach slips recovery—single item

Response: 1 (strongly agree) to 4 (strongly disagree).
(a) If a person forgets to use bleach to clean his or her works, he or she can use will power to use bleach the next time.

Self-efficacy (single items)

Confidence to carry out 8 specific behaviors in the next 3 months.
Response choices: 1 (extremely confident), 2 (somewhat confident), 3 (not very confident), 4 (not at all confident).
(a) You could avoid using any drugs.
(b) If you were shooting drugs, you could refuse someone who wanted to share your needles.
(c) If you were shooting drugs and had to share works, you could always clean your works with bleach.
(d) You could always carry bleach with you, "just in case."
(e) You could stay away from people who insist on sharing needles.
(f) You could always carry a condom with you "just in case."
(g) You could always use a condom during sex.
(h) You could "talk yourself out of" doing something which would increase your AIDS risk.

Continued on next page

APPENDIX—Continued.

Psychomotor Skills

Cleaning works with bleach

Range 0 to 3 based on the number of actions completely carried out during demonstration. Each of the following criteria was scored as .5. Completely filling:

(a) the syringe with bleach
(b) the syringe with water the first time
(c) the syringe with bleach the second time
(d) the syringe with water the second time
(e) the cooker with bleach (at least one time)
(f) the cooker with water (at least one time)

Condom use

Range 0 to 1 based on whether respondent pinched the tip of the condom prior to rolling it down on a penis model.

*The detailed algorithm for the weighting of responses can be obtained from the authors
**Scales were computed as the unweighted sum of the items. Item scores were reversed as necessary so that a high score on the scale indicates greater agreement with the construct.

Awards for Excellence in Asthma Control

The First National Conference on Asthma Management is soliciting nominations for awards for excellence in asthma control. The following awards will be presented:

1. *National Asthma Award for Biomedical Research,* awarded for leadership and contributions in research that have led to a better understanding of basic biologic mechanisms in asthma.

2. *National Asthma Award for Clinical Research,* awarded for leadership and contributions in clinical research that have led to major advances in the management of asthma.

3. *National Asthma Award for Health Education Research,* awarded for leadership and contributions in health education research that have emphasized the importance of the patient-physician partnership as the cornerstone of effective asthma management.

4. *National Asthma Award for Public Education/Service,* awarded for leadership in the development of and/or contributions to community asthma programs, patient education, or increased public awareness about asthma.

One award will be presented in each of the above categories. Recipients will be selected by a distinguished awards jury of leaders in the field of asthma research and control. Nominations for the awards must be postmarked by July 1, 1992. For more information, contact the First National Conference on Asthma Management, PO Box 30105, Bethesda, Maryland 20824-0105. Tel: 301/951-3275.

HIV Infection in Intravenous Drug Users Entering Drug Treatment, United States, 1988 to 1989

ABSTRACT

Background. Intravenous drug use has played a key role in the human immunodeficiency virus (HIV) epidemic. Standardized surveillance of HIV infection among intravenous drug users (IVDUs) is needed to determine HIV prevalence rates, to monitor changes in prevalence over time, and to describe behaviors associated with HIV infection.

Methods. In 1987, the Centers for Disease Control began collaborating with state and local health departments to conduct a national program of HIV seroprevalence surveys in a variety of populations and settings. This program includes unlinked HIV seroprevalence surveys in IVDUs entering sentinel drug treatment programs.

Results. From April 1988 through December 1989, annual studies were completed in 59 drug treatment centers in 33 US cities. Center-specific seroprevalence rates ranged from 0% to 48.2%, with a median of 4.6%. HIV seroprevalence rates varied widely by geographic area, with rates highest in the Northeast, intermediate in the Middle Atlantic cities of Baltimore and Washington, DC, and lower in other parts of the country. Median rates were 15.6% among African Americans, 3.2% among Hispanics, and 3.3% among Whites.

Conclusions. Intravenous drug use is likely to remain an important factor in HIV transmission. This study supports the need to develop or expand programs to prevent the further introduction and spread of HIV among IVDUs and to prevent HIV transmission to their sexual partners. (*Am J Public Health.* 1992;82:541–546)

David M. Allen, MD, MPH, Ida M. Onorato, MD, Timothy A. Green, PhD, and the Field Services Branch of the Centers for Disease Control

Introduction

From 1981 through June 30, 1991, the Centers for Disease Control (CDC) received reports of 39 904 cases of acquired immunodeficiency syndrome (AIDS) in heterosexual intravenous drug users (IVDUs), 11 823 cases of AIDS in homosexual and bisexual men who reported intravenous drug use, 5305 cases in heterosexual partners of IVDUs, and 1847 cases in infants born to mothers who were IVDUs or the sexual partners of IVDUs. These cases associated with intravenous drug use represent 32.2% of all AIDS cases.

Because of the lengthy incubation period between the human immunodeficiency virus (HIV) infection and the diagnosis of AIDS,[1] reported AIDS cases do not necessarily represent the current scope or the recent patterns and trends of the HIV infection. In 1987, the CDC reviewed published and unpublished information on HIV seroprevalence among IVDUs in treatment programs in the United States.[2] In the reviewed studies, the HIV seroprevalence rates varied by geographic location, race/ethnicity, and other demographic variables. However, these rates were difficult to interpret because of differences in study methodology.

In 1987, the CDC began collaborating with state and local health departments to conduct a national program of HIV seroprevalence surveys in a variety of populations and settings.[3,4] These surveys, conducted annually, include assessing HIV prevalence among persons attending sentinel drug treatment centers in selected metropolitan areas.

Standardized serological surveillance of IVDUs is needed to determine levels of HIV infection, to monitor changes in prevalence over time, and to describe behaviors associated with HIV infection. Furthermore, these data are needed to project future health care needs and formulate public health policy.

IVDUs entering treatment programs are the most accessible group of all IVDUs for unlinked ("blinded") surveys because, upon entry into drug treatment, many clients receive a routine medical assessment, which entails, among other things, the collection of blood specimens. IVDUs entering drug treatment can serve as an indicator group for monitoring the levels and trends of HIV infection among drug users in the United States. This report describes the serosurveillance system for HIV in IVDUs and presents findings from the first two years of operation.

Methods

Survey methods for this study are described in detail elsewhere.[5] In brief, cities are selected to participate in clinic-based HIV seroprevalence surveys based on (1) the cumulative number of AIDS cases, (2) syphilis and gonorrhea case rates, (3) geographic location, and (4) willingness of

David M. Allen and Ida M. Onorato are with the HIV Seroepidemiology Branch and Timothy A. Green is with the Statistics and Data Management Branch of the Centers for Disease Control (CDC) in Atlanta, GA. state and local health departments to participate. Drug treatment centers within these cities are selected by state and local health departments based on criteria that include the existence of procedures for routine medical assessment of new clients, the characteristics of the populations served, and geographic location. By mid-1990, 114 centers in 44 metropolitan areas had participated in the surveys.

In unlinked surveys, HIV-1 antibody tests are performed on the unused portion of blood specimens collected for other routine purposes. Blood specimens from clients entering treatment programs who have used drugs intravenously in the previous 12 months are eligible for inclusion. General demographic information (sex, age, race or ethnicity, and zip code of residence), as well as the primary intravenous drug used, is recorded for each client on standardized survey forms, each of which is assigned a precoded study number. Self-reported sexual behaviors and sexual orientation are also recorded for clients in centers where this information is routinely collected. Personal identifiers (e.g., client's name, address, and clinic chart number) are removed from the blood specimen, which is labeled with the same study number; only then is the blood specimen tested for antibodies to HIV-1.

Data forms and HIV test results are sent to a designated metropolitan area survey coordinator, who links test results and demographic data. To further ensure anonymity, only summary data—without individual test results—are returned to the clinic.

Blood specimens from eligible clients are sequentially collected until the predetermined survey sample size is achieved. We recommend a sample size of 500 clients per center, or continuous sampling during a 12-month period for centers in which fewer than 500 clients are enrolled. Subsequent annual surveys will be conducted during the same months of the year.

Specimens are tested for antibodies to HIV at designated laboratories using an HIV-1 enzyme immunoassay licensed by the Food and Drug Administration (FDA) and according to manufacturer's recommendations. Specimens that are repeatedly reactive are then tested by an FDA-licensed Western blot assay. Western blot band patterns are interpreted according to recommendations of the Association of State and Territorial Public Health Laboratory Directors and the CDC. Participating laboratories take part in the CDC program of quality assurance.

Participating state and local health departments analyze their data using CDC-designed computer software. Data are also shared with the CDC for regional and national analyses. For each drug treatment center, HIV seroprevalence rates are calculated by demographic (race/ethnicity, sex, age) and other variables, including the primary drug used and treatment modality, for all clients combined. We designated the median among the rates for participating centers in each city as the seroprevalence rate for that city. The median is the point that half of the observations fall above and half fall below.

For this report, we restricted analyses to those centers with 50 or more blood specimens collected from April 1988 through December 1989. Rates by sex, race and ethnicity, age group, and primary drug used were calculated only for those centers with more than 25 specimens for each subgroup. Comparisons of seroprevalence rates were made using the Mantel-Haenzel test.

Results

Through December 31, 1989, 59 drug treatment centers in 33 cities had tested 50 or more eligible samples each. A total of 16 237 blood specimens from these centers were tested for antibodies to HIV-1, of which 2201 were Western blot positive. By center, seroprevalence rates ranged from 0% to 48.2%, with a median rate of 4.6% (Table 1). Six centers reported rates under 1%, and 7 centers reported rates over 30%. Rates varied widely by geographic area, with rates highest in the Northeast, intermediate in the Middle Atlantic cities of Baltimore and Washington, DC, and lower in other parts of the country, including Hawaii (Figure 1). Data were not available from Miami or Puerto Rico. The median HIV seroprevalence rate for centers in the Northeast was 25.8% compared with 2.6% for centers in the remainder of the United States. Within the Northeast, the highest rates were seen in Newark and New York City. Rates decreased to the north and south of these metropolitan areas.

Sex

Of the total study population, 66% were males and 34% were females. Among all centers, the median rate for males was 5.4% (range: 0% to 50.0%) and for females, 4.4% (range: 0% to 50.0%) (Table 1). After controlling for differences among centers and age groups, there were no statistically significant differences between male and female seropositivity rates. In selected cities, especially those with high seroprevalence rates (i.e., Boston, Camden, Baltimore, and Washington, DC), rates were higher in women than in men; these differences, however, were not statistically significant after controlling for age.

Race

Table 2 lists HIV seroprevalence rates by race/ethnicity by city. For all centers, median rates were 15.6% for African Americans, 3.2% for Hispanics, and 3.3% for Whites. African Americans had a significantly ($P < .001$) higher seroprevalence rate than Whites after controlling for center. Among those 33 centers in 22 cities with both African-American and White drug users tested, the median rates were 16.9% and 4.3%, respectively. Hispanics had a significantly ($P < .002$) higher seroprevalence rate than Whites after controlling for center. For those 19 centers in 12 cities with both Hispanic and White drug users tested, the median rates were 3.4% and 4.2%, respectively. Although the median rates are similar, the rate among Hispanics exceeds 15% in eight centers and 30% in five centers, whereas the rate among Whites exceeds 15% in six centers and 30% in only one center.

Age

Preliminary graphic analysis indicated that the effect of age on HIV seroprevalence rates is different for high versus low seroprevalence centers. As a result, we categorized centers into three groups based on HIV seroprevalence rates. Group 1 (n = 28) included centers with HIV seroprevalence rates from 0.0% to 9.9%, group 2 (n = 12) included centers with rates from 10.0% to 21.5%, and group 3 (n = 7) included centers with rates of 21.6% and above. Figure 2 shows the relationship between seroprevalence rate and age group. After controlling for center there were significant age-group effects, with HIV seroprevalence rates increasing with age through age 40 in groups 2 ($P < .01$) and 3 ($P < .001$) but not in group 1. When the 20- to 24-year-old age group was omitted from the analysis, however, the age-group effect in group 2 was only marginally significant ($P < .04$).

Primary Drug and Treatment Modality

Heroin was the primary drug used for 13 499 clients in 52 centers, and cocaine was the primary drug for 899 clients in 9

centers. Median center-specific seroprevalence rates for heroin users was 5.4% (range: 0.0% to 48.2%) and for cocaine users, 8.3% (range: 1.1% to 18.8%).

Twenty-two cities had centers where clients admitted to treatment listed heroin alone as the primary drug used. A small number of clients chose other drugs as the primary drug used. Five cities had centers that permitted the comparison of heroin with cocaine as the primary drug used. In none of these centers were the differences in seroprevalence rates statistically significant.

Methadone detoxification or maintenance was the treatment modality for most clients (Table 3). HIV seroprevalence was higher in clients entering cocaine and drug-free treatment compared with those entering methadone detoxification or methadone maintenance. These rates, however, are based on small sample sizes.

Sexual Orientation

Of all the centers, three collected information on the sexual orientation of new clients and included 10 or more homosexual or bisexual men or women. The three centers include a total of 61 bisexual or homosexual women, 55 bisexual or homosexual males, 346 heterosexual women, and 764 heterosexual males. HIV seroprevalence rates for homosexual or bisexual men in these three centers were 21.4%, 21.7%, and 44.4%, compared with 4.3%, 14.0%, and 3.4% for heterosexual men in the same centers. These differences were statistically significant in two of the three centers ($P < .05$). Rates for homosexual or bisexual women were 0.0%, 0.0%, and 3.0%, compared with 2.9%, 1.1%, and 2.1% for heterosexual women in the same clinics. These differences were not statistically significant.

Discussion

Data from the surveys of IVDUs entering treatment indicate that HIV seroprevalence is strongly associated with geographic location, with rates highest in the Northeast. This geographic pattern may be due to several reasons, including the earlier entry of HIV in intravenous drug-using populations in the Northeast; differences in both the availability of sterile injection equipment and the prevalence of drug use behaviors that facilitate HIV transmission, such as the use of "shooting galleries";[6] and differences in the development and characteristics of HIV prevention programs. The reasons for higher HIV prevalence in IVDUs in the Northeast and lower prevalence in the remainder of the United States, however, require further clarification.

HIV seroprevalence rates in IVDUs also vary by race and ethnicity, with rates higher in African Americans and Hispanics than in Whites. This pattern is consistent with that seen for drug use–associated AIDS.[7] The magnitude of the differences in HIV seroprevalence between African Americans and Whites was inconsistent, however, and varied by city.

There were no significant differences in HIV seroprevalence rates in IVDUs by sex. Although this finding is in contrast to differences in the proportion of AIDS cases by sex, HIV seroprevalence studies of IVDUs, especially those in high-prevalence areas, have shown similar prevalence rates in males and females.[8,9]

In centers with HIV seroprevalence of at least 10%, rates increased with age. This may be due to several reasons, including the risk of HIV in clients entering treatment with a longer history of drug use compared with younger clients, or the aging of a cohort of IVDUs that was previously infected with HIV.

Self-reported information on sexual behaviors and sexual orientation is not routinely collected upon entry into drug treatment. In the three centers where this information is collected, the data indicate that bisexual or homosexual male IVDUs have higher HIV seroprevalence than heterosexual male IVDUs. Although the data are limited, they suggest that sexual ori-

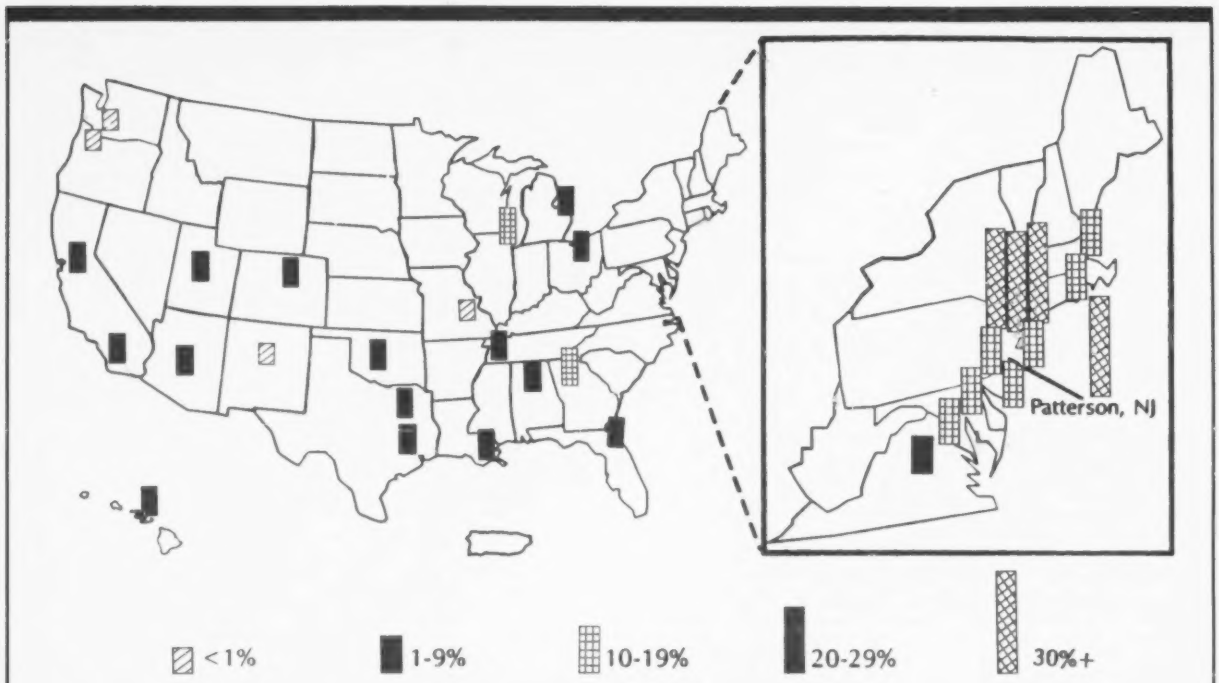

FIGURE 1—Median HIV seroprevalence in drug treatment centers, United States, 1988–1989.

entation and sexual behaviors should be ascertained as part of the routine clinical assessment of the risk of HIV for persons entering drug treatment. Men who report sexual activity with men may require additional or specialized HIV prevention efforts.

There are several considerations in the interpretation of these data. First, the seroprevalence rates, although indicative of patterns throughout the country, are truly representative of only those centers studied. This survey, however, contains the only national collection of blood specimens with standardized protocols for IVDUs entering treatment. Second, because participating clinics do not constitute a probability sample of all drug treatment facilities (nor is such a sample feasible), the data are illustrative rather than representative of HIV seroprevalence in IVDUs entering drug treatment throughout the United States or in a given metropolitan area. Third, the study includes sera only from IVDUs entering drug treatment and not from those who do not seek treatment. While these biases make it difficult to generalize sentinel clinic data to all IVDUs in an entire metropolitan area, repeating the surveys annually should keep most clinic-specific biases constant over time. The resulting data should reflect HIV seroprevalence trends over time for these clinics and assist locally in the development and evaluation of prevention programs.

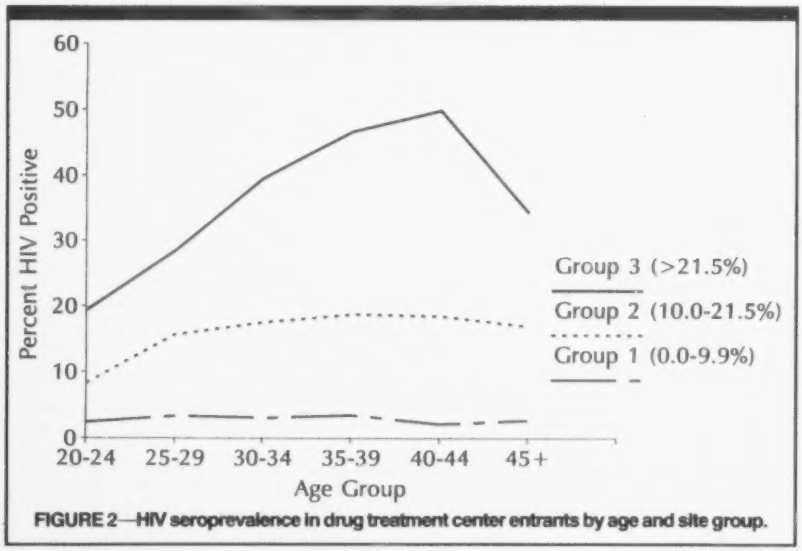

FIGURE 2—HIV seroprevalence in drug treatment center entrants by age and site group.

Current federal requirements stipulate that a routine medical assessment that includes the collection of blood specimens take place upon a person's entry to methadone treatment. Other treatment programs, including those for cocaine or amphetamine use, may not require blood collection prior to treatment. Drug treatment centers that do not routinely collect blood during client admission are not eligible to conduct unlinked surveys. As a result of these requirements, most of the participating centers represented in this report offer methadone treatment. HIV seroprevalence rates in clients receiving

other treatment modalities are therefore less adequately accounted for here.

Limited demographic and risk behavior data are available in unlinked surveys. These surveys indicate the need for additional information on factors associated with the initiation of drug use; behaviors associated with HIV infection, such as the frequency of drug use; and the possible reasons for increased rates in certain geographic areas and among selected racial and ethnic minorities.[10] In particular, higher rates among selected racial and ethnic minority groups compared with rates among Whites may be mediated by other factors, such as socioeconomic status or geographic location within metropolitan areas. Selected drug treatment centers conducting unlinked seroprevalence surveys also conduct risk behavior surveys in which consenting clients are interviewed in detail regarding potential risk behaviors. These linked surveys will complement the unlinked studies and may suggest further preventive measures aimed at changing high-risk behaviors and reaching the sexual partners of IVDUs who may be at risk of HIV infection.

Intravenous drug use has been associated with explosive increases in HIV transmission in the New York City area in the early 1980s[11] and more recently in parts of Europe[12] and Asia.[13] Because the potential for such an explosion also exists in parts of the United States where HIV prevalence is low, sentinel surveys provide an important early warning system to indicate changes in HIV prevalence among drug users throughout the United States. In clinics offering voluntary HIV testing and counseling, unlinked surveys can also be used to indicate the degree to which HIV-infected clients are included in testing and counseling programs.

HIV transmission in IVDUs, their sexual partners, and their babies remains an important public health problem, and continued efforts should be made to develop programs designed to prevent the transmission of HIV to uninfected IVDUs and to the sexual partners of IVDUs. Intravenous drug use is likely to remain the most critical factor associated with HIV in women and in heterosexual and perinatal transmission. Use of sentinel HIV surveillance data can assist in developing programs to prevent the introduction and spread of HIV among IVDUs and their sexual partners. □

International Lactation Consultant Association Announces 1993 Manuscript Competition

The International Lactation Consultant Association is sponsoring a 1993 competition designed to identify outstanding manuscripts relating to human lactation or breastfeeding. Authors may enter one of two categories: a literature review competition or a research paper competition. The winner in each category will receive $500 (US). Winning manuscripts will be published in the *Journal of Human Lactation.* Entrants need not be members of the International Lactation Consultant Association. Students are encouraged to enter.

Competition in the research paper competition is open to published or unpublished authors; authors entering the literature review competition is limited to currently unpublished authors. The postmark deadline for entry in the 1993 competition is January 5, 1993.

To obtain specific information regarding this manuscript competition, send a self-addressed (and stamped if US) envelope to K. G. Auerbach, PhD, IBCLC, Editor-in-Chief, Journal of Human Lactation, 1993 Manuscript Competition—Dept. AP, 2240 Willow Road, Homewood, IL 60430-3221, USA.

HIV Prevalence and Risk Behavior among Injecting Drug Users Who Participate in "Low-Threshold" Methadone Programs in Amsterdam

ABSTRACT

Introduction. After the onset of the HIV epidemic, the hope arose that the "harm reduction" approach of the Amsterdam "low-threshold" methadone programs would have a function in controlling the spread of HIV among injecting drug users (IDUs).

Methods. To find evidence for this assumption, 386 IDUs participating in an HIV study between 1985 and 1989 were studied. Long-term regular participants in low-threshold methadone programs were compared with short-term and/or irregular participants.

Results. Controlling for possible confounders, long-term regular participants had a slightly increased but not statistically significant risk of being HIV infected. With regard to current drug use, they injected daily and shared needles as often as did short-term and/or irregular participants.

Conclusions. The results suggest that the Amsterdam low-threshold methadone programs fail to diminish HIV risk behavior. If these programs want to have a positive effect on the spread of HIV, expansion of existing HIV prevention efforts, an increase in the daily methadone dose level, and measures to enforce regular attendance may be required. (*Am J Public Health.* 1992;82:547–551)

Introduction

Methadone treatment for intravenous heroin users can help reduce the risk of infection with the human immunodeficiency virus (HIV). The magnitude of this reduction depends on the ability of methadone programs to reduce illicit opiate injecting.[1–5]

The Amsterdam "low-threshold" methadone programs endeavor to take down the barriers that treatment programs and/or methadone maintenance programs[6,7] put up for drug users (DUs) by not prohibiting illicit use of opiates or other drugs. This enables these programs to contact many active DUs who do not want to quit drug use. Low-threshold programs do not aim at treating the addiction; instead, they aim primarily at contacting heroin users and regulating or stabilizing their use by preventing withdrawal symptoms. Within the "harm reduction" approach,[8,9] the programs' function is to signal and take care of sociomedical problems in an early phase. Together with social support, this approach should provide a foundation on which initiatives to quit drug use will have a better chance of succeeding.[10]

After the onset of the HIV epidemic, the hope arose that low-threshold methadone programs would have a function in controlling the spread of HIV,[9,11] either by informing active DUs about the HIV risk or through the prescription of methadone, which would stabilize addiction and lifestyle and thereby reduce injecting. The present study aims at evaluating the effect of the Amsterdam low-threshold programs on HIV risk behavior and on the spread of HIV among injecting drug users (IDUs) participating in an epidemiological study of HIV infection.

Methods

Low-Threshold Methadone Programs

An estimated 5000 to 6000 DUs were in Amsterdam in each quarter of 1985 to 1989.[12,13] Among them, approximately 40% had injected in the previous month. The Drugs Department of the Municipal Health Service operates seven low-threshold methadone clinics,[12–14] which daily provide on-site primary medical and social care and supply methadone to a yearly population of about 3500 DUs. Nonresidents get methadone only when it is medically indicated or when it is needed to enable the user to return to the city or country of origin.

Illicit opiate or cocaine use is not a reason for dismissal from the program. Neither is discontinuation of the program for several days, although a reintake (which entails seeing a doctor) is then required. If clients want to quit drug use, they either enter a methadone reduction scheme with urine screening for opiates or are directed to a treatment clinic. Regulated DUs get methadone prescribed by their general practitioner. Between 1981 and 1984, the flow to general practitioners was approximately as large as the opposite flow.[14]

TABLE 1—Logistic Regression Model of Predictors of HIV Infection among Amsterdam IDUs[a]

	Adjusted Odds Ratio (n = 377)	95% Confidence Interval
First occurrence of injecting		
<5 years ago	1	
≥5 years ago	2.39	1.27–4.47
Last occurrence of injecting		
≥6 months ago	1	
<6 months ago	1.91	0.98–3.75
Frequency of borrowing[b]	1.21	0.99–1.48
Mainly heroin and cocaine injecting in the previous 5 years		
No	1	
Yes	2.13	1.30–3.49
German or South European[c] nationality	3.53	1.61–7.77
Other, incl. Dutch	1	
Time living in Amsterdam[d]	1.42	1.20–1.68

[a]Only IDUs that had no missing values on any of the variables used in the analysis (n = 377) were included.
[b]Values: 0 = never, 1 = 1 time, 2 = 2–9 times, 3 = 10–99 times, 4 = 100 times or more; a value of x is associated with a risk of being HIV seropositive that is 1.21 times higher than a value of x–1.
[c]French, Spanish, Italian, Greek, Portuguese, or Yugoslav.
[d]Values: 1 = no time or <1 year, 2 = 1–<2 years, etc., to 6 = ≥5 years; a value of x is associated with a risk of being HIV seropositive that is 1.42 times higher than a value of x–1.

In 1987, the average daily methadone dose in the low-threshold programs was approximately 35 mg (range: 5 to 120 mg). Doses between 60 and 120 mg were prescribed in about 3% of cases. The average yearly duration of methadone supply for Dutch DUs was 21 weeks.

Study Population and Variables

In 1985 an epidemiological study of HIV infection among DUs[15–17] was initiated. This ongoing study involves voluntary, confidential HIV antibody testing and counseling for DUs, combined with an interview by specially trained nurses using a standard demographic/behavioral questionnaire. DUs enroll in the study through a low-threshold methadone clinic or through a sexually transmitted diseases clinic for addicted prostitutes. Most DUs entering the study (83%) have at some time injected; 55% have injected in the month before entering.

The present study concerns all 386 DUs who had injected drugs at some time (hereafter called "injecting drug users," or IDUs) and who enrolled in the study through low-threshold methadone clinics from December 1985 until March 1989.

Interviews and serological tests were completed for all 386 IDUs; 110 (28%) were HIV seropositive. The mean age of the 386 IDUs at entrance was 29.7 years (standard deviation = 5.9, range: 16 to 57); 260 were male (67%) and 126 female (33%); and 311 (81%) were Dutch.

Limited data are available on DUs who get methadone on prescription in Amsterdam[12,13] but are not available specifically on IDUs. With regard to age, there was no significant difference between the 386 study participants and all DUs who got methadone on prescription in Amsterdam in 1987. The male/female ratio in the study was 2:1, as compared with 3:1 among DUs attending low-threshold methadone clinics in 1987.

Behavior reported over the 6 months preceding the interview is called "current" behavior. Behavior in the period prior to these 6 months as far back as 5 years before the interview is indicated as occurring "in the previous 5 years." Current IDUs who started injecting at least 5 years ago are called "long-term IDUs." The variable frequency of borrowing used needles concerns the full 5 years preceding the interview. Long-term regular methadone users (LTM users) were defined as IDUs who started using methadone at least 5 years preceding the interview and who reported daily methadone use in the 5 years preceding the interview. The non–LTM users were defined as IDUs who started using methadone less than 5 years preceding the interview and IDUs who reported irregular use of methadone during these 5 years. Time of the interview was divided into four consecutive periods of 10 months each: (1) December 1985 to September 1986, (2) October 1986 to July 1987, (3) August 1987 to May 1988, and (4) June 1988 to March 1989.

Statistical Analysis and Serology

Statistics used were χ^2, Student's t, Spearman rank correlation coefficient, Mann-Whitney test, odds ratios (ORs), and 95% confidence intervals (CIs).[18] P values (two sided) of less than .05 were taken as significant. Logistic regression models were used to determine the independent contribution of different characteristics in predicting HIV serostatus. All demographic and drug use variables that had a univariate statistically significant association with HIV serostatus were considered for entry into the model. Three injecting variables (first and last occurrence of injecting and frequency of borrowing) were considered crucial and were entered at the first step. At each further step, the variable that contributed most to the prediction of HIV serostatus was selected. To provide estimates of the statistical association between LTM use and HIV infection while controlling for possible confounders, adjusted ORs and CIs were derived from logistic regression coefficients. Serological tests used for HIV testing were enzyme-linked immunosorbent assays and/or immunoblotting.[16]

Results

Predictors of HIV Infection

A model was built (see Methods) that optimally could predict HIV serostatus. First occurrence of injecting, injecting mainly heroin and cocaine in the previous 5 years, nationality, and time living in Amsterdam were significantly associated with HIV infection (see Table 1).

Differences between LTM Users and Non–LTM Users

One hundred and ninety four IDUs (50%) met the criteria for LTM use and 189 (49%) fell in the non–LTM group (3 IDUs had missing data). Table 2 shows the differences between the two groups with regard to duration and regularity of methadone use. Compared with non–LTM users on demographic and drug use variables, LTM users are older, more often male, and more often Dutch; they have lived longer in Amsterdam, started injecting longer ago, and inject mainly heroin less often and cocaine, either by itself or together with heroin ("speedball"), more often (see Table 3).

LTM users inject daily as often as non–LTM users. Among the 189 non–LTM users, 135 persons (71%) currently use methadone daily and 54 persons (29%) do not (see Table 2). The proportion of current daily injectors is also similar in these subgroups: 49 of 135 (36%) versus 19 of 54 (35%). Frequency of borrowing and reuse of own needles and syringes are similar among LTM and non–LTM users (see Table 3).

LTM users have a higher HIV prevalence than non–LTM users: 37% versus 20% (OR = 2.42, CI = 1.54–3.83). There is a positive relation between number of years since the first methadone prescription and being HIV positive ($P = .005$). The higher seroprevalence of LTM users is found in each of the four consecutive time periods: for LTM users it is 35%, 49%, 28%, and 32%, respectively, as compared with 21%, 16%, 24%, and 18% among non–LTM users.

Controlling for Possible Confounding

To control for possible confounding, the variable of LTM use was entered in a logistic regression model together with the variables of age, sex, German or South European nationality, time living in Amsterdam, first occurrence of injection, and last occurrence of injection, with HIV serostatus as a dependent variable. The adjusted OR was 1.60 (CI = 0.93–2.74), indicating a slightly—but not statistically significant—increased risk of being HIV seropositive for LTM users.

As we considered duration of injecting an important possible confounder, we explored the relation between LTM use, HIV risk behavior, and HIV serostatus separately in the subgroup of 223 long-term IDUs. Among these IDUs, duration and regularity of methadone use in the 133 LTM users and 90 non–LTM users were similar to what was found in the total sample (see Table 2). With regard to demographic and drug use variables, the differences (and similarities) between the 133 LTM users and 90 non–LTM users were the same as in the total group, with one exception: the proportion of males among LTM users and non–LTM users are the same. As in the total sample, the 133 LTM users are more often HIV positive than the 90 non–LTM users (43% vs 28%; OR = 1.97, CI = 1.10–3.52). Adjusted for age, sex, nationality, and time living in Amsterdam, the OR for LTM use was 1.34 (CI = 0.69–2.63).

To exclude possible confounding due to exposure to HIV before coming to Amsterdam, we did a separate analysis among Dutch IDUs who were Amsterdam residents for at least 5 years. In this subgroup of 230 IDUs, the 147 LTM users differ from the 83 non–LTM users on four demographic and drug use variables: LTM users are older, started injecting longer ago, currently inject more often, and inject mainly cocaine more often. With regard to current daily injecting, having borrowed at least 10 times, and current borrowing, there are no significant differences between LTM users and non–LTM users. LTM users are again more often HIV positive than non–LTM users (38% vs 21%; OR = 2.39, CI = 1.22–4.71). Adjusted for age, sex, and first and last occurrence of injecting, the OR was 2.06 (CI = 1.02–4.16).

HIV infection may have been the reason for long-term participation in low-threshold methadone programs. To exclude this potential bias, we added the variable daily methadone use to a separate multivariate logistic regression analysis of incident HIV infections.[19] The behavior of 31 IDUs, who were HIV-seronegative at entrance into the study but who seroconverted for HIV during follow-up, was compared with that of 202 randomly selected controls, who remained seronegative throughout their follow-up period. In

TABLE 2—Duration and Regularity of Methadone Use of LTM users and Non–LTM users among Amsterdam IDUs

	LTM users (n = 194)	Non–LTM users (n = 189)
Mean number of years (SD) since first methadone prescription	8.4 (3.2)	2.9 (2.6)
(Median, range)	(7, 5–20)	(2, 0–17)
Daily methadone use in the previous 6 months (%)	100	71
Daily methadone use in period before this (for LTM users, up to 5 years before the interview; for non–LTM users, since first methadone prescription, no more than 5 years preceding intake) (%)	100	60

TABLE 3—Demographic and Drug Use Characteristics of LTM users versus Non–LTM users among Amsterdam IDUs (n = 383[a])

Characteristics	LTM users (n = 194)	Non–LTM users (n = 189)	Significance[b]
Mean (median) age (y)	31.0 (31)	28.3 (28)	$P < .001$
	# %	# %	
Male sex	145 (75)	113 (60)	$P < .002$
Dutch nationality	172 (89)	136 (72)	$P < .0001$
Living >2 years in Amsterdam	181 (93)	127 (67)	$P < .0001$
First time injected ≥5 years ago	162 (84)	118 (62)	$P < .0001$
Currently injecting (<6 months ago)	158 (81)	139 (74)	ns
Currently injecting			
mainly heroin	22 (11)	39 (21)	$P < .01$
mainly cocaine	17 (9)	14 (7)	ns

Currently daily injecting	75 (39)	68 (36)	ns
Daily injecting in previous 5 years	139 (72)	130 (69)	ns
Currently having borrowed	80 (42)	73 (39)	ns
Having borrowed ≥10 times in previous 5 years	73 (38)	67 (36)	ns
Currently reusing same needle and syringe	82 (42)	81 (43)	ns

[a]As a result of missing data, the effective total sample varies from 378 to 383 subjects. Percentages are calculated with the effective sample as denominator.
[b]Statistics used: to test for differences in mean age, *t* test; for other variables, χ^2 (with $df = 1$) or Mann-Whitney test. Ns = not statistically significant.

univariate analysis, daily methadone use, reported over a mean period of 8 months preceding the first visit after seroconversion or the selected control visit, was not "protective" (OR = 0.67, CI = 0.31–1.47). When the variable daily methadone use was adjusted for the independent risk factors for HIV seroconversion, its OR became 0.81 (CI = 0.35–1.83).

Discussion

An important finding of the present study is that IDUs participating in low-threshold programs who report long-term daily use of methadone engage in similar or even more HIV risk behavior than IDUs who use methadone for a shorter time and/or irregularly. Univariately, being HIV seropositive is associated with LTM use and with the number of years since the first methadone prescription. In contrast, studies from other countries have reported that DUs in long-term methadone maintenance have a lower HIV seroprevalence than DUs not in treatment,[20-24] which suggests that these maintenance programs are successful in protecting IDUs from HIV infection. In the present study, the HIV prevalence of LTM users who entered the study before October 1986 (i.e., in the first time period) is 35%. These IDUs started using daily methadone before 1981. Because HIV prevalence among 145 DUs entering low-threshold programs in 1983 and 1984 was only 3.4%,[25] presumably HIV hardly circulated among DUs in 1981. This indicates that these LTM users got infected mainly while enrolled in the low-threshold programs.

The present study has some limitations. First, the short average duration of yearly methadone supply in low-threshold methadone programs (21 weeks) suggests that, in reality, LTM users did not use methadone continuously in the 5 years preceding intake. Due to privacy regulations, it is impossible to validate our data with data from the methadone program records. Thus, it is unknown whether the actual yearly duration of methadone use in the total sample significantly differs from our data. Nevertheless, we hold it possible that the self-reports overestimate the actual duration of methadone use. For the present study, it is assumed that LTM users were supplied with methadone more continuously—and during a much longer time—than non–LTM users.

Second, because no data on IDUs in low-threshold programs are available, the representativeness of the sample is unknown. However, although our sample is not atypical for low-threshold program participants with regard to number of years of methadone use[13,26] or age, males are underrepresented in the present study.

Third, comparing methadone users with non-users, preferably randomly assigned, would have been more appropriate. However, to find a group of comparable IDUs who have never used methadone is—within the Amsterdam context—impossible: only young or newly starting injectors have never used methadone, and so random assignment was not feasible.

Finally, HIV-seropositive IDUs may have entered the study preferentially—for example, because of health problems. However, all IDUs in the present study entered before March 1989, when zidovudine or prophylaxis for Pneumocystis carinii pneumonia or tuberculosis was not yet given to DUs in the Netherlands. Thus, DUs seemed to enter the study because of HIV risk through injecting, not because of health problems.

With regard to demographics, LTM users were found to be more often Dutch and to have lived a longer time in Amsterdam than non–LTM users. This is in agreement with the intake rules of low-threshold programs, which discourage nonresident drug users from participating.

With regard to drug use, current daily injecting is similar for LTM and non–LTM users, as is borrowing of needles and syringes. LTM users inject mainly heroin less often and inject cocaine, either by itself or together with heroin, more often. A similar relation was found previously; Chaisson et al.[27] reports that methadone treatment reduces heroin injecting more strongly than it does cocaine injecting. Speedball injecting is associated with an increased HIV risk, both in the present sample and in New York City.[28]

To summarize, there were no indications that LTM users engaged in less HIV risk behavior than non–LTM users. Furthermore, when we looked at the effect of LTM use on HIV risk, while controlling for confounders, we found no indication of a protective effect of LTM use. The same was true in a separate analysis of incident HIV infections[19]: a protective effect of daily methadone use could not be identified.

These findings suggest that the low-threshold programs do not have an effect on HIV risk because risk behavior is not reduced. Another possibility is that a risk reduction takes place shortly after the start of methadone prescription but does not grow over the years. In contrast, in a prospective study among IDUs in US methadone maintenance programs,[7] the prevalence of injecting declined from 81% at the beginning of admission to 63% at the end of the period. After this prevalence declined gradually to 42% in the third year and 29% in the fourth year of participation. However, no such decline is apparent in our sample.

To conclude, our results do not support the view that long-term regular participation—as compared with short-term and/or irregular participation—in low-threshold methadone programs in Amsterdam is associated with less HIV risk–injecting behavior or with a decreased risk of HIV. The apparent failure of the programs to reduce such behavior may be due to the low average methadone dose level or to the (permitted) irregular attendance.[1,2,29] However, raising methadone doses to a level at which little or no illicit opiate use occurs, combined with measures to increase attendance, may lower the number of clients, given that not all DUs wish to stop illicit use. Such measures thus would counteract the possibility of providing medical and social care to a large group of DUs, many of whom are HIV seropositives.

It therefore seems necessary to judge carefully the relative merits of the low-threshold approach versus other kinds of approaches. In any case, we suggest that contacts with IDUs in the low-threshold programs should be used more intensively for HIV prevention efforts and that an increase in methadone dose level, together with measures to enforce regular attendance, may be required if these programs want to play a role in HIV prevention. □

Acknowledgments

This study was supported by the Netherlands Foundation for Preventive Medicine (grant no. 28–1258). The authors thank the nurses B. Frolich, B. Scheeringa-Troost, G. Stienstra, and J. The Potential Role of Custody Facilities in Controlling Sexually Transmitted Diseases

Deborah Cohen, MD, MPH, Richard Scribner, MD, MPH, John Clark, MD, MPH, and David Cory

ABSTRACT

Background. **The National Commission on Correctional Health Care recommends that medical screening, including tests for syphilis and other sexually transmitted diseases, be performed by the 14th day after initial booking procedures. Because the average length of stay in detention is usually less than 14 days, most detainees are not screened or treated for asymptomatic communicable diseases.**

Methods. **In order to determine the incidence and prevalence of syphilis among those booked through a large county jail, a rapid screening procedure to test newly incarcerated inmates and treat those infected was implemented over a 3-week period.**

Results. **Among 6309 detainees eligible for testing during the 3-week period of the study, 129 (2%) were diagnosed with syphilis. During the preceding month when only those reporting symptoms or high-risk behaviors were screened, 20 cases were diagnosed. The sensitivity and predictive value of self-reported risk factors for syphilis infection were low. Among the first 110 diagnosed cases, 17 (15.5%) were released within 3 days and 86 (78%) were released within 6 days.**

Conclusion. **If screening and treatment for syphilis are delayed until the 14th day after booking, the majority of infected inmates will be released prior to evaluation and treatment. Rapid screening and treatment for selected sexually transmitted diseases are likely to be an effective public health measure when implemented in custody settings. (*Am J Public Health.* 1992;82:552–556)**

Introduction

Several studies have documented the high prevalence of sexually transmitted diseases (STDs) among persons in custody facilities.[1–3] Screening for STDs among both adult and juvenile offenders is mandatory in some states and is recommended by the American Medical Association.[4] The National Commission on Correctional Health Care recommends that medical screening or review of medical screening be performed on or before the 14th day after initial booking procedures.[5] Because the average length of stay in detention is usually less than 14 days,[6] most persons arrested are not screened or treated for asymptomatic communicable diseases. Even when screening is performed at the time of booking, results may not be available until after the inmate has been released. Subsequently, those at risk may not be located and treated. Considering the rapid turnover of inmates in the custody setting, rapid screening, diagnosis, and treatment may significantly reduce STD morbidity.

Background

Beginning in 1986, Men's Central Jail (MCJ), the main custody facility for men in Los Angeles County (LAC), offered a serologic test for syphilis (STS) on admission only to persons who self-identified any of several risk factors, i.e., homosexuality, history of STD, intravenous drug use, and current symptoms of STD. This policy was instituted primarily to reduce costs. It was assumed that the yield of true positives would be greater through a self-identification process. In addition, all inmates would receive a full health appraisal after 2 weeks of residence.

In 1988, cases of syphilis reported from custody facilities comprised more than 10% of the county's early syphilis morbidity, even though fewer than 10% of the persons booked through custody facilities were tested.[7] The LAC jails comprise the largest custody facilities in the United States, booking approximately 250 000 persons annually and having about 25 000 residents on any given day.[6]

In order to determine the incidence and prevalence of syphilis among those booked through MCJ and to establish a risk profile of infected inmates that might be more objective than self-identification, a 3-week project to test newly incarcerated inmates was implemented. Because inmates who are released are difficult to locate for further evaluation and treatment, the protocol included immediate STS results and treatment prior to release.

Methods

Between March 29, 1989, and April 19, 1989, the Sexually Transmitted Disease Program of the Los Angeles County Department of Health Services provided a "stat" rapid plasmin reagin (RPR) test to all inmates booked at MCJ between 6 PM and 4 AM, Monday through Friday, when

This paper was submitted to the journal September 14, 1990, and accepted with revisions April 4, 1991.

the majority of men held for at least 24 hours are processed.

Because syphilis screening in custody facilities is mandated by law, all inmates were asked to submit to phlebotomy. Inmates who refused to have their blood drawn were separated from the others and referred for an interview and exam by project staff. To obtain a random subsample of nonreactor inmates for comparison, the third inmate whose RPR was nonreactive out of a batch of 10 to 15 specimens tested was also evaluated. A venereal disease research laboratory (VDRL) test and a confirmatory microhemagglutination assay for *Treponema pallidum* (MHA-TP) was performed on all inmates with reactive RPR as well on nonreactor controls.

Demographic data including age, race, and criminal charges were obtained from custody records. Public health nurses administered a questionnaire assessing sexual behavior, history of sexually transmitted diseases, and drug use. Physicians examined inmates with a history of symptoms or a reactive RPR. Inmates with reactive tests were interviewed for contacts, and named contacts were referred for field follow-up by health department investigators. Record searches through the Los Angeles County Venereal Disease Record System (VDRS) were performed for all persons with confirmed reactive serologies to compare prior titers and verify a history of prior diagnosis and treatment.

An inmate was classified as having primary syphilis if the physicians documented a typical chancre, regardless of RPR result. A diagnosis of secondary syphilis was made based upon typical lesions and confirmed reactive treponemal tests. Early latent syphilis was diagnosed if the patient had a reactive serology confirmed by a reactive MHA-TP, a history of typical lesions or negative serology in the previous 12 months or sexual contact with another case of early syphilis, and no documentation or history of treatment. Any asymptomatic inmate who had a confirmed reactive RPR, had no history of treatment, or did not fall into the previous categories was diagnosed with late latent syphilis. A case was defined as the presence of untreated syphilis, regardless of stage.

Inmates with reactive RPR, no history of treatment, or physical findings consistent with syphilis were offered treatment with benzathine penicillin G or with doxycycline in case of penicillin allergy. Those with a history of prior treatment or a weakly reactive RPR and no physical findings were treated at the discretion of the project physicians.

All data were analyzed using the Statistical Analysis System (SAS) and Epi-Info, which uses the Cornfield method for determining odds ratios (ORs) and confidence intervals (CIs).

TABLE 1—Race-Specific Rates of Infectious Syphilis among Men Booked at Men's Central Jail, Los Angeles County, March 26–April 19, 1989

Race/ Ethnicity	N	Infectious Syphilis	Early Latent Syphilis	Late Latent Syphilis	Total Syphilis
Whites	1292	0 (0)	0 (0)	1 (77)	1 (77)
Blacks	2135	21 (984)	22 (1030)	24 (1124)	67 (2998)
Hispanics	2632	11 (418)	21 (798)	27 (1026)	59 (2242)
Asians	84	0 (0)	0 (0)	0 (0)	0 (0)
Other/Unknown	166	0	0	2	2
Total	6309	32 (507)	43 (682)	54 (856)	129 (2045)

Note. Data are number of cases (rate per 100 000).

Results

Population Description

During the 3-week project period, 12 147 men were booked through MCJ. The study population comprised 6309 men who were booked for at least 24 hours between 6 PM and 4 AM and offered an STS. Of these, 95 refused phlebotomy, leaving 6214 men tested. The remaining 5867 inmates not in the study sample were either booked during daytime hours or were immediately released on their own recognizance. No data are available for this group.

The study population was predominantly Black and Latino (75.6%). The average age was 30. Forty-eight percent of the inmates were charged with alcohol- or drug-related offenses, 22.2% with theft-related charges, 9.6% with crimes of violence, 7.2% with traffic violations, and 1.5% with crimes related to sexual behavior. The majority of the study group said they lived in LAC.

Rates of Syphilis

Of the men screened for syphilis, the RPR was reactive in 308 (4.9%). Physicians reported active lesions in 32 persons, one of whom had a nonreactive RPR and was diagnosed because he had been part of the interviewed nonreactor group and had symptoms. Another case of primary syphilis was found in an inmate who had refused the blood test but was examined. Untreated syphilis was identified in 129 men for a rate of 2045/100 000. The rate of infectious syphilis was 507/100 000. (The county-wide rate was 45.1/100 000 in 1988.) Early latent syphilis was diagnosed in 43 men for a rate of 682/100 000. The race-specific rate for early syphilis was highest among Blacks (2014/100 000). Fifty-four men had latent syphilis infection of unknown duration which we classified as late latent syphilis (Table 1). Of the 308 men with reactive RPRs, 75 (24%) had a negative MHA-TP and 84 (27%) were patients who had a history of prior treatment for syphilis.

Time of Release of Cases

Among the first 110 diagnosed cases, 17 (15.5%) were released within 3 days and 86 (78%) were released within 6 days. Twenty-one of the 233 inmates with a reactive MHA-TP were not available for further evaluation and so a diagnosis could not be made for them.

Risk Factors

Because of time and security constraints, inmates with reactive RPRs were preferentially evaluated over nonreactors. Among reactors, 278/308 (90%) were evaluated, among refusers 33/95 (35%), and among nonreactors, 372/531 (70%).

Ninety-eight percent of all cases were either Black or Latino and their risk of syphilis was, respectively, 41.7 and 29.6 times that of Whites. Cases were more likely than noncases to have a history of syphilis, gonorrhea, or any STD and were more likely than controls to have had three or more sex partners in the previous 90 days (OR=3.46, 95% CI=1.48–8.26). Only three cases (2.3%) and four nonreactors (1.1%) admitted to ever having sex with other men. These seven men said they also had sex with women. Cases were more likely to be between the ages of 31 and 40 (Table 2). Inmates with syphilis were less likely to be married and more likely to say they had less education than nonreactors.

TABLE 2—Characteristics of Study Sample

Characteristic	Cases n (%)	Noncases[a] n (%)	OR (95% CI)[b]
Race			
White	1 (0.8)	1289 (20.9)	1.00
Black	67 (51.9)	2070 (33.5)	41.72 (7.21–1,673.46)
Hispanic	59 (45.7)	2573 (41.6)	29.56 (5.09–1,187.89)
Asian	0 (0)	84 (1.4)

[a]Noncases are all inmates with no diagnosis of syphilis.
[b]OR=odds ratio; CI=confidence interval.

There was no association between booking charge and syphilis infection.

Only 3 of the 32 inmates with infectious syphilis identified themselves as having symptoms at the time of entry into the study. In a confidential setting, an additional 15 men said they had a genital "sore" or ulcer. Upon examination, 5 of these men did not have syphilitic lesions.

Cases were more likely than nonreactors to say they regularly used smokable crack cocaine (OR=2.07, 95% CI=1.16–3.69). No other drug was associated with syphilis cases more than with noncases. The sensitivity and positive predictive value of the hypothesized risk factors obtained in a confidential setting were low (Table 3).

Refusers

Compared to cases, the 33 refusers were more likely to be White (21% vs 1% of cases), to be married (27% vs 13%), and to say they had had a blood test for syphilis in the previous 12 months (39% vs 15%).

False-Positive Results

Among 75 inmates who had false positive RPR results, 44.7% reported regular heroin use and 70% said they had tried heroin at least once. These inmates were older than cases (average age=36.5 years) and more of them were White (24% vs 1%). They were more likely to say they had a history of syphilis or "bad blood" (23% vs 8%) and more likely to have been booked for alcohol-related charges (35% vs 11%).

Contact Interviewing and Tracing

Of the 308 patients with reactive, qualitative RPRs, 187 were interviewed by investigators. During the interview process, 29 said they had been treated previously and another 29 were subsequently found not to be infected based on a negative MHA-TP. Interviewers elicited 93 new contacts from 60 interviewed inmates with early syphilis. Of these, 31 (33%) were located during field follow-up. Eight of the contacts had early syphilis. Field investigations were initiated for acquaintances of reactors who were pregnant. Out of eight pregnant women named, the only one found infected was a prostitute with secondary syphilis. Preventive treatment was given to 19 contacts. One contact had been previously treated and one refused evaluation. The overall contact index (number of contacts elicited per case) was 1.6, and the disease intervention index (percentage of cases where at least one contact was treated[8]) was 0.32.

Discussion

This study documents a 2% rate of syphilis among inmates booked through Los Angeles County's Men's Central Jail and the feasibility and effectiveness of integrating rapid screening and treatment into the booking process. In the month prior to the screening project, 20 cases of syphilis were reported by the jail compared to 129 cases during the 3-week project.

Usefulness of Risk Factor Identification

The attempt to identify factors that could be used to select out the highest risk inmates with a high degree of sensitivity and specificity was unsuccessful. In the jail setting with criminal charges pending, inmates are unlikely to bring special notice to themselves or to be forthright about behaviors that are illegal. Although the study verified that a history of gonorrhea or syphilis and the presence of symptoms elicited in a confidential setting were associated with syphilis, these risk factors had low sensitivity and positive predictive value. Other risk factors such as homosexuality and heroin use did not appear as risk factors, probably because so few admitted to these behaviors.

Risk factors identified through the case-reference methodology included the use of crack cocaine, three or more sex partners in the previous 90 days, history of syphilis or gonorrhea, and less than 10th-grade education. However, if a screening program depended on obtaining a history of drug use or high-risk sexual behavior in a confidential setting, approximately half of the infected cases would be missed. Given the rapidity with which men are booked, the crowded conditions, and the lack of confidential settings in the county jail, individual history taking for all inmates is not feasible.

Race (i.e., being Black and Latino) was the risk factor with the highest sensitivity (98%) for syphilis, reflecting the county-wide trend in Los Angeles: compared to Whites, Blacks were at a 30-fold and Hispanics at an 8-fold greater risk of being reported with infectious syphilis.[9]

Limitations

We could not interview all members in the reference group; however, there was no difference between the reference group and the entire population in the distribution of race, age, and booking charge.

We believe there was no systematic bias in selecting the reference group and our findings are likely to be generalizable to the entire population of men booked at night for criminal offenses in Los Angeles.

Recommendations

The criminal justice setting may be one of the few public institutions in which there is an opportunity to break chains of infection among high-risk populations. Rapid screening and treatment of STD in custody facilities should be considered public health control measures in localities with a high incidence of STDs. When the development of antibiotic resistance is not a concern and the incidence of serious adverse reactions is minimal, all inmates with laboratory evidence suggestive of disease should be empirically treated. In our study we treated very few inmates whose qualitative RPR was weakly reactive. Eleven inmates subsequently had titers ≥1:16 and reactive MHA-TP tests but could not be found for treatment.

Contact tracing was generally unproductive. The achieved disease intervention index (0.32) compares poorly to expected national standards of 0.60. Results might have been higher if the interviewer had been the person assigned to field follow-up. Given the morbidity and mortality of congenital syphilis, intensive efforts to locate only contacts or suspects who are pregnant may be useful.

While we have not explored the feasibility of screening and treatment for other STDs such as gonorrhea and chlamydia, the prevalence of these STDs is likely to be higher[1] and the cost of screening men with the leukocyte esterase dipstick substantially lower than with the RPR.[10] Syphilis, gonorrhea, and chlamydia have been found to be potential risk factors for human immunodeficiency virus (HIV) disease.[11–13] A substantial reduction in morbidity might occur, not only for transmission of HIV, but also for other sequelae such as infertility, pelvic inflammatory disease, and ectopic pregnancies.[14]

Few public resources are devoted to providing preventive medical care for persons charged with criminal offenses; yet, the public health impact of treating a large infected population is likely to be enormous in decreasing the chance that many other individuals in the community will become infected. Population-based screening of groups characterized by the societal conditions associated with high-risk behavior and lack of access to health care, such as socioeconomic status, race, and place of residence, is likely to be more effective in limiting STDs than control programs that require individuals to identify themselves to be at risk and to actively seek screening and treatment. □

Workshop on Statistics & Computing in Disease Clustering to Be Held July 23 & 24, 1992, in Stony Brook, NY

Applied Biomathematics, with funding from the Electric Power Research Institute and the National Cancer Institute, is conducting a 2-day workshop on statistical methods and computer resources for disease clustering. This field is changing rapidly and novel approaches for analyzing clusters are frequently proposed. The aim of this workshop is the active involvement of the participants in discussion of the following areas:

Scientific Merit How should clustering methods be selected, and what can clustering studies offer?

Cluster Allegations How should we deal with post hoc data analyses?

Cluster Patterns How can patterns in space and time be characterized?

Methods What is the power of clustering techniques under different space–time arrangements of cases?

Applications What research needs are revealed by past analyses?

GIS How can geographic information systems and geographic statistics be used to identify links between environment and health?

Resources What databases and microcomputer software are currently available for cluster investigations?

Contributed papers are solicited on these or related topics. The program committee consists of Dr. Geoffrey Jacquez, Applied Biomathematics (chair); Dr. Roger Grimson, Department of Preventive Medicine, SUNY at Stony Brook; Dr. Leeka Kheifets, Electric Power Research Institute; and Dr. Daniel Wartenberg, Robert Woods Johnson Medical School.

This workshop will bring together those who develop statistical and computational methods with those who use them. Workshop information may be obtained from Dr. Jeffrey A. Millstein, Applied Biomathematics, 100 North Country Road, Setauket, New York 11733. Tel: 516/751-4350; Fax: 516/751-3435.

Occupational Injuries among Minors Doing Farm Work in Washington State: 1986 to 1989

Nicholas J. Heyer, PhD, Gary Franklin, MD, MPH, Frederick P. Rivara, MD, MPH, Paul Parker, JD, and Joanna A. Haug, MS

ABSTRACT

Background. There is growing evidence that many children are injured while engaged in agricultural work. However, little specific information on farm work–related injuries among minors is available, probably because employment or workers' compensation data for children are hard to obtain.

Methods. Workers' compensation data were used to evaluate occupational injuries among children in Washington State from 1986 through 1989. The frequency and severity of injuries among minors doing farm work were compared with the distributions of injuries among minors working in food service and all other occupations by year of injury, age of injury, and month and hour of injury.

Results. A total of 16 481 claims filed by children under age 18 were evaluated. Although farm workers accounted for only 7% of all claims, they made up 36% of claims filed by children under age 14, and 17% of claims filed by children aged 14 or 15. Injuries classified as serious accounted for 26% of farm worker claims compared with only 16% of all claims filed by children.

Conclusions. Although injury rates could not be developed owing to the lack of denominator data, this study demonstrates that farm work is dangerous for young children. (*Am J Public Health.* 1992;82:557–560)

Introduction

Agriculture is one of the most hazardous industries in the United States, sharing with mining and construction the highest rates of occupational mortality.[1] Yet young children frequently work on farms and are subject to this risk. It has been estimated that 14% to 24% of all fatal injuries on farms (occupational and nonoccupational) occur among children 15 years of age or younger,[1] and that persons 19 years of age or younger are involved in 25 000 nonfatal traumatic events and 300 injury deaths on farms annually in the United States.[2]

Although numerous reports have looked at farm injuries among children in various states,[1,3–11] few have focused specifically on occupational (i.e., work-related) farm injuries among children. Two hospital-based reports on farm injuries among minors tried to focus on work-related injuries by excluding drownings, shootings, and poisonings. These reports demonstrated high levels of injury severity (largely due to involvement with machinery).[4,11] A study of fatal injuries involving tractors reported that 29% occurred among children aged 19 or younger.[7]

Methods

The Washington State workers' compensation program (administered by the state's Department of Labor and Industries) covers all employers with one or more full- or part-time employees. Major exemptions include employees covered by some other compensation program (e.g., federal, police and fire fighters') or, for agricultural employment, family members of the farm owner who are minors (under 18 years of age). Workers' compensation coverage may be through self-insurance or the State Fund. Two thirds of nonfederally employed workers in Washington State are covered by the State Fund.[12]

All claims for workers' compensation filed by minors through the State Fund were reviewed for the 4 years, 1986 through 1989. Claims filed for either injury or occupational disease were included because it is often difficult to distinguish between the two. However, disease claims represent less than 4% of all claims.[13]

The following data elements were used for our analysis:

1. US Bureau of Census Occupation Codes,[14] to define farm workers (code 479) and food service workers (codes 435 through 444). All claims not in one of these two categories were coded as "all others." Farmers (code 473), farm managers (code 476), and farm supervisors (code 477) were not included among farm workers, as they do not represent the farm employment of interest.
2. Age at time of injury, categorized into three groups: 13 years of age

Nicholas Heyer and Joanna Haug are with the Occupational Epidemiology and Health Outcomes Program of the University of Washington's Department of Environmental Health in Seattle, and Frederick Rivara is with its School of Medicine. Paul Parker is with the State of Washington's Department of Labor and Industries. Gary Franklin is affiliated with all three institutions.

This paper was submitted to the Journal December 4, 1990, and accepted with revisions September 20, 1991.

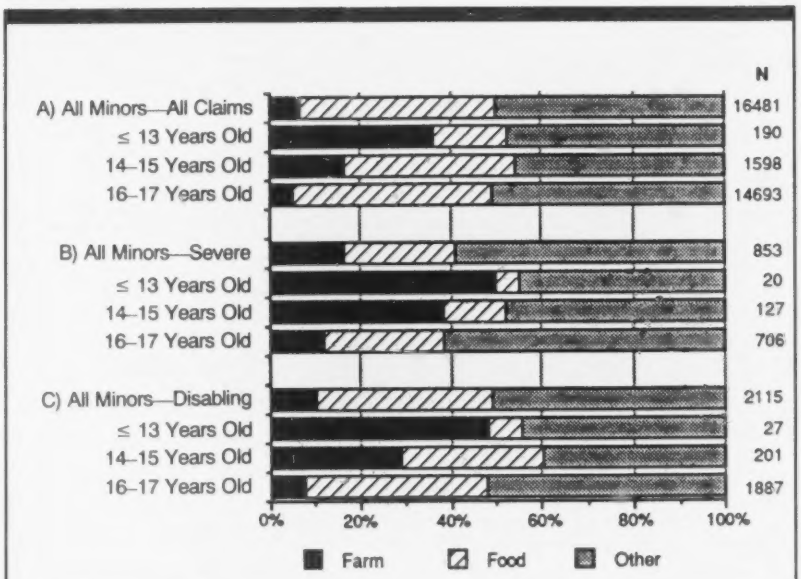

FIGURE 1—Distribution of occupations within age groups for all claims, severe claims, and disabling claims.

or younger, 14 or 15 years of age, and 16 or 17 years of age.

3. Year of injury.
4. Month of injury, coded to season: winter (December, January, and February), spring (March, April, and May), summer (June, July, and August), and fall (September, October, and November).
5. Hour of injury, coded to AM (after midnight through noon) or PM (after noon and through midnight).
6. Serious injuries, defined using two independent, surrogate measures: nature of injury and time loss payment (made by the State Fund after the loss of 4 or more days of work). Nature of injury was recorded using the American National Standards Institute Z-16 codes.[15] Only injuries with code 100 (amputations), code 110 (asphyxiation or drowning), code 140 (concussion), code 210 (fracture), or code 400 (multiple injuries) were considered to be "severe." All injuries with time loss payments were considered to be "disabling."

Specifically, the workers' compensation records were used to examine the frequency and severity of claims among minors employed as farm workers. Although rates were not estimated because total employment data are not maintained for minors, the distribution of claims among minors in farm worker, food service, and all other occupations was evaluated, as the distribution of claims among injuries classified severe, disabling, or both. The relationships between injuries, season, and time of day of injury were also evaluated because of the nature of farm employment and its potential interaction with school performance.

Results

All Claims

A total of 916 475 claims were filed with the Department of Labor and Industries during this 4-year period, with 16 481 (1.8%) filed by minors. Of the claims filed by minors, 190 (1.2%) were filed by children aged 13 or younger, 1598 (9.7%) by children aged 14 or 15, and 14 693 (89.2%) by children aged 16 or 17.

Figure 1 shows the distribution of occupations for all claims by age group. Although farm workers represent less than 7% of all claims filed by minors, they account for 36% of claims filed by children aged 13 or younger and for 17% of claims filed by children aged 14 or 15. By comparison, food workers represent 43% of all claims filed by minors, of which only 16% were filed by children in the youngest age group and 38% by children aged 14 or 15.

Serious Injuries

A total of 2617 (15.9%) claims filed by minors were for serious injuries (severe, disabling, or both). Among farm worker claims, 26% were for serious injuries. The relative frequencies of claims for severe and disabling injuries, severe only injuries, and disabling only injuries were all higher among farm workers than among food service workers or all other workers (Figure 2). The differences were greatest for the youngest age groups. Among farm workers, serious injuries accounted for 25% of all claims filed by children aged 13 years or younger and for 30% of all claims filed by children aged 14 or 15. By comparison, the percentages for food service workers were 12% and 6.5%, respectively.

Farm work contributes substantially to the total number of severe or disabling injuries among the two youngest age groups. Among workers aged 13 or younger, farm work accounted for 50% of all severe injury claims and for 48% of all disabling injury claims, compared with 5.0% and 7.4%, respectively, among food service workers. Among workers aged 14 or 15, farm workers accounted for 39% and 29% of severe and disabling injury claims, respectively, compared with 13% and 31% for food service workers (Figure 1 b and c).

Variation by Year and Season

There is no consistent pattern of variation in claims for minors by year and occupation. However, among food service workers, the two youngest age categories have almost doubled their proportion of claims, from 6.4% in 1986 to 12.4% in 1989.

There is, however, considerable variation by season for all occupational categories, especially for farm workers (Figure 3). The summer quarter accounts for 68% of all farm worker claims, compared with 38% of all food service worker claims and 52% of all other claims. The summer quarter also represents a disproportionately high percentage of claims among the two youngest categories of children (13 years of age or younger, or 14 or 15 years of age), who together account for 36% of all farm worker claims, 11% of all food service worker claims, and 13% of all other occupational claims.

Variation by Time of Day

Figure 4 shows the distribution of claims by time of day (AM/PM) within season for the three occupational categories. Farm workers filed claims for injuries occurring in the morning 58.9% of the time, compared with only 21.3% for food service workers and 36.2% for all other occupa-

tional claimants. During the three seasons when school is in session (i.e., excluding summer), the percentage of farm worker claims filed for morning injuries ranged from 32.4% to 56.0%, compared with a range of 18.8% to 19.6% for food service workers and of 26.0% to 28.4% for all other occupational claimants.

Discussion

The descriptive information obtained from Washington State's workers' compensation data about farm injuries among minors must be viewed as preliminary, given that no rates could be developed owing to the lack of denominator data. However, the data are consistent with previous reports in demonstrating that injuries related to farm work tend to have high levels of severity and that a substantial number of these injuries is occurring among young children.[4,7,11]

The distribution of all injuries, and of serious injuries by age, was compared for minors in farm work, in food service, and in all other occupational categories. The proportion of total claims filed among minors aged 13 or younger and among minors aged 14 or 15 is greater for farm workers than for food service workers and all other workers. This could be due to either a greater percentage of young minors being employed as farm workers or a greater percentage of those young minors employed as farm workers being injured, or both.

Furthermore, the proportions of severe injury claims, disabling injury claims, and both severe and disabling injury claims are all much higher among farm workers in all age categories than among food service workers and all other workers. The proportion of serious injury claims is particularly high among farm workers aged 14 or 15 (more than 30% of all claims). The proportion of serious claims among minors engaged in farm work is twice that among those employed in food service or all other employment. Unless minors employed in food service and other nonfarm employment file twice as many claims overall as those employed in farm work, the unmeasured, underlying rate of serious claims among minors employed in farm work will be greater.

Independent of any assumptions, it is clear that farm work accounts for a considerable proportion of all claims, especially serious injury claims among children aged 13 or younger and among children aged 14 or 15. Farm workers account for 49% of serious injury claims (severe, disabling, or both) among children aged 13 years or younger and 30% of such claims for children aged 14 or 15.

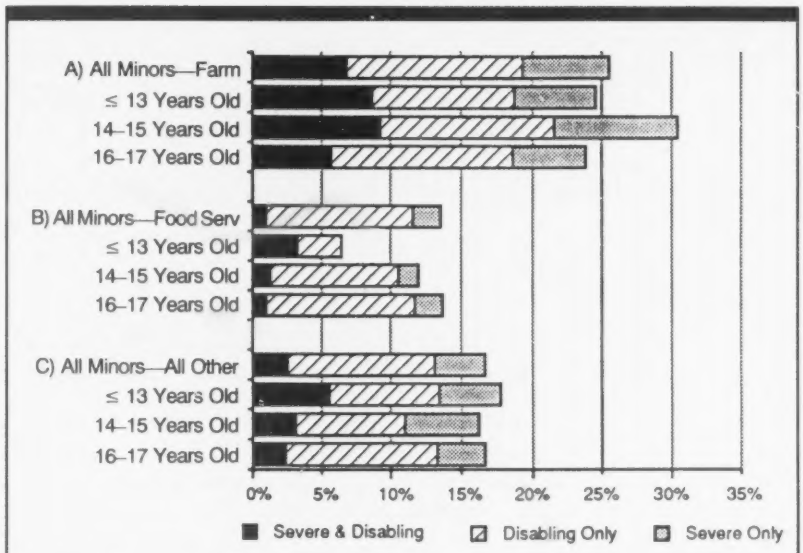

FIGURE 2—Percentage of severe and/or disabling claims within occupation and age groups.

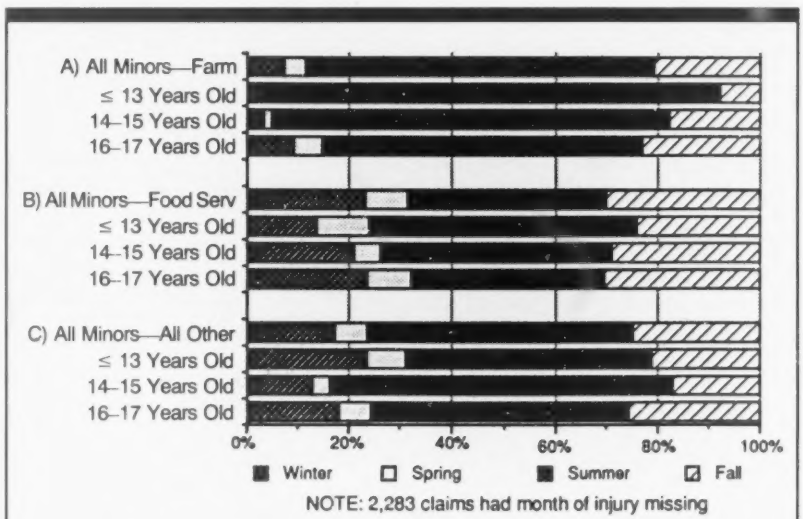

FIGURE 3—Distribution of claims by season within occupation and age groups.

Although no temporal trends for injury claims among farm worker minors could be identified, the proportion of claims among the two youngest categories of minors doing food service work nearly doubled between 1986 and 1989. This may represent that there has been a shift to younger employees or that more hazardous work is being performed by the youngest employees in the food service industry. This trend should be monitored.

The diurnal distribution of claims was also reviewed. A much greater percentage of farm worker injuries occurred in the morning during the winter and fall months when compared with injuries for food service employment or all other employment (Figure 4). This high percentage of morning claims suggests that farm worker minors (1) are working long hours before going to school, (2) are at particularly high risk during preschool working hours, (3) are working during morning school hours, or (4) are engaged in some combination of the above. Further investigation in regard to these factors and their possible interaction with the perceived high rate of school dropouts or

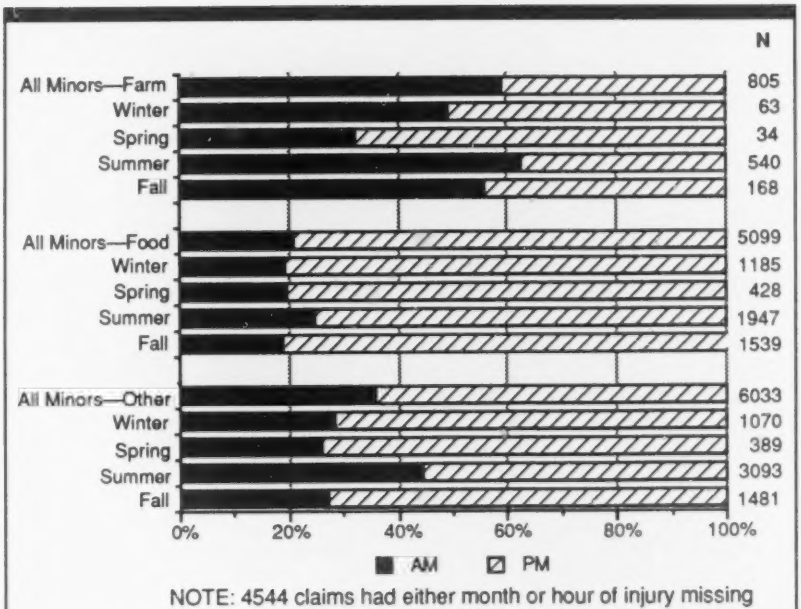

FIGURE 4—Distribution of claims by time of day and season within occupational group.

failure among farm worker children[16] requires further critical appraisal.

Concern about the potentially negative impact of farm work on the health and school performance of minors is not new. The data presented here were generated in support of the rule-making process that is currently ongoing in Washington State concerning employment of minors. Rules recently adopted by the Department of Labor and Industries[17] exceed federal standards in many respects. The state will prohibit minors under age 14 (who are not members of the farm owner's family) from doing farm work except for summer hand harvesting and cultivation of four crops (berries, flower bulbs, cucumbers, and spinach). The regulations will limit the number of hours minors can work per day and per week, and they will prohibit the work minors can do during certain night and early morning hours.

Using workers' compensation data has several drawbacks. First, injuries are likely to be underreported because only those injuries resulting in the filing of a claim are recorded. The underreporting is likely to be more severe for farm injuries than for other employment categories (especially food service, in which child labor is well established and occurs largely in well-supervised, national chains). Thus, the data presented here probably underestimate the farm injury problem. Second, the unavailability of data to directly evaluate rates of injuries among minors is of concern. The fact that worker hours are not reported for minors in general, and for farm worker minors in particular, is a major methodological problem in addressing the issues raised in this paper. □

Acknowledgments

This work was funded by the Accident and Medical Aid Funds of the Washington Department of Labor and Industries. These research monies are targeted to reducing the incidence of and disability related to occupational injuries and illnesses.

Impact of HIV Infection on Mortality and Accuracy of AIDS Reporting on Death Certificates

Nancy A. Hessol, MSPH, Susan P. Buchbinder, MD, David Colbert, Susan Scheer, MA, Ronald Underwood, MD, MPH, J. Lowell Barnhart, Paul M. O'Malley, Lynda S. Doll, PhD, and Alan R. Lifson, MD, MPH

ABSTRACT

To assess the impact of HIV infection on mortality and the accuracy of AIDS reporting on death certificates, we analyzed data from 6704 homosexual and bisexual men in the San Francisco City Clinic cohort. Identification of AIDS cases and deaths in the cohort was determined through multiple sources, including the national AIDS surveillance registry and the National Death Index. Through 1990, 1518 deaths had been reported in the cohort and 1292 death certificates obtained. Of the 1292 death certificates, 1162 were for known AIDS cases, but 9% of the AIDS cases did not have HIV infection or AIDS noted on the death certificate. Only 0.7% of the decedents had AIDS listed as a cause of death and had not been reported to AIDS surveillance. AIDS and HIV infection was the leading cause of death in the cohort, with the highest proportionate mortality ratio (85%) and standardized mortality ratio (153 in 1987), and the largest number of years of potential life lost (32 008 years). The devastating impact of HIV infection on mortality is increasing and will require continued efforts to prevent and treat HIV infection. (*Am J Public Health.* 1992;82:561–564)

Introduction

To monitor the impact of specific diseases on mortality in the United States, accurate death certificate information is essential. Such accuracy is important for precise monitoring of mortality trends from acquired immunodeficiency syndrome (AIDS) and possible identification of unrecognized conditions associated with human immunodeficiency virus (HIV) infection. Recently, several US studies, using information from death certificates, have examined the impact of HIV infection and AIDS on mortality.[1–5] These studies are limited by lack of specific risk-group information. Additionally, few studies have been able to assess the accuracy of AIDS reporting on death certificates[5,6] because it is difficult to link US AIDS surveillance and vital statistics registries.

In this analysis, we obtained information on HIV infection, reported AIDS diagnosis, and deaths among a San Francisco cohort of homosexual and bisexual men. Our objectives were to describe underlying causes of death; to assess underreporting of AIDS on death certificates; and to calculate cause-specific proportionate mortality ratios (PMRs), years of potential life lost (YPLL), and standardized mortality ratios (SMRs) for deceased cohort members.

Methods

The San Francisco City Clinic cohort consists of 6704 homosexual and bisexual men recruited between 1978 and 1980 from the municipal sexually transmitted disease clinic for studies of hepatitis B.[7,8] In 1980, hepatitis B vaccine trials began. Unused serum samples from these studies were frozen and stored. In 1983 we began AIDS follow-up studies in this cohort.

All participants reported to have AIDS were considered HIV antibody positive prior to death. For men who died of causes other than AIDS, stored specimens were tested for HIV antibody.

To identify AIDS cases in the cohort, we cross-matched with San Francisco and national AIDS surveillance registries. To identify deaths among cohort members, we gathered information from San Francisco and national AIDS surveillance registries, newspaper obituaries, San Francisco Vital Statistics, and the National Death Index.

Death certificates were obtained from San Francisco Vital Statistics and state registrars. All causes of death and other significant conditions were coded according to the current International Classification of Diseases ninth revision coding manual (ICD-9 CM).[9] According to this system, underlying causes of death are assigned AIDS-related codes only when HIV infection or AIDS is noted. For this analysis, underlying cause of death

Total	109

was determined according to the National Center for Health Statistics guidelines.[10]

Cause-specific PMRs were calculated as the number of deaths from a particular cause divided by the total number of deaths in the cohort. To evaluate temporal trends, cause-specific PMRs were calculated by year of death. The YPLL for each deceased cohort member was calculated by subtracting the age at death from 65 years. Summing the YPLL of all decedents dying of a particular cause gives the cause-specific YPLL. For the years 1981 and 1987, age-adjusted cause-specific death rates within the cohort were compared with United States data,[11] and SMRs were used to measure the ratio of the observed number of deaths to the expected number of deaths.

Results

Through 1990, 1518 deaths had been reported in the cohort and 1292 death certificates obtained. The median year of death was 1987 (range 1978–1990) and the median age at death was 37 years (range 22–76). The racial/ethnic distribution was 92% White, 4% Latino, 3% African American, and 1% other, similar to the distribution of the cohort as a whole.[7,8] Death certificates were obtained from 39 US states and territories. The majority, 1097 death certificates, came from California, including 919 from San Francisco.

The most common underlying cause of death was HIV infection (Table 1). Of the 1292 decedents, 1194 were HIV antibody positive prior to death, 85 were HIV negative at their last blood test, and 13 had no previous HIV antibody results. The percentage of men who were HIV-positive prior to death was highest among those who died of infectious or parasitic diseases and lowest among those who died of liver disease, suicide, or injuries.

Among the 1162 death certificates obtained for men who had previously been reported to AIDS surveillance, 1053 (91%) had HIV or AIDS noted. The most common underlying causes of death in the remaining 9% were neoplasms, immunodeficiency, and infectious and parasitic diseases (Table 2). Among the 1063 decedents with HIV or AIDS noted on the death certificate, only 7 had not been previously reported to AIDS surveillance.

The PMRs for the five most common causes of death are shown in Table 3. The PMR was 84.6% for HIV infection, 3.4% for suicide, and less than 3% for all other causes. Over time, the PMR for HIV infection increased from 0% in 1978–1981 to 14% in 1982, 62% in 1984, 82% in 1986, 88% in 1988, and 93% in 1990.

The cause-specific YPLL was 29 123 for men with HIV or AIDS mentioned on the death certificate, 1251 for suicide, 980 for malignant neoplasms, and less than 900 for all other causes (Table 3). The total YPLL for all AIDS-related deaths, includ-

ing deaths occurring in men identified either through AIDS surveillance or AIDS on the death certificate, was 32 008.

Age-adjusted cause-specific SMRs for the year 1981 show excess mortality for HIV infection and immune disorders (Table 4). SMRs for 1987 reveal a higher than expected rate for HIV infection and immune disorders and for suicide.

TABLE 3—Proportionate Mortality Ratios (PMRs) and Years of Potential Life Lost (YPLL) for the Five Leading Causes of Death, San Francisco City Clinic Cohort, 1978–1990

Cause of death (ICD-9 code)	PMR	YPLL
HIV infection (042–044)	84.6	29 123
Suicide (E950–E959)[a]	3.4	1 251
Malignant neoplasms (140–208)[a]	2.9	980
Unintentional injuries (E800–E949)[a]	2.1	830
Other infectious and parasitic diseases (001–041, 045–139)[a]	2.1	729
AIDS-related subtotal (includes all AIDS cases)		32 008
Total, all causes		35 546

[a]Includes reported AIDS cases

TABLE 4—Age-Adjusted Cause-Specific Standardized Mortality Ratios (SMRs) and 95% Confidence Intervals (CIs) for Years 1981 and 1987, San Francisco City Clinic Cohort

Cause of Death	SMR (95% CI) 1981	SMR (95% CI) 1987
HIV infection and immune disorders[a]	127.7 (3.2–696)	153.5 (131–179)
Suicide	0.6 (.02–3.5)	3.4 (1.1–7.9)
Malignant neoplasms	1.3 (.15–4.6)	1.1 (.2–3.1)
Unintentional injuries	0.4 (.05–1.6)	0.3 (.01–1.7)
Other infectious and parasitic diseases	6.7 (.17–37.1)	0

95% confidence intervals were calculated using the Poisson distribution.[14]
[a]Due to temporal changes in both the ICD-9 coding system and the Centers for Disease Control AIDS case definition, these two leading causes of death were combined.

Discussion

In the 1986–1987 US population, injuries and heart disease were the most common underlying causes of death among white men aged 25 to 44.[11] Our findings from the San Francisco City Clinic cohort show a different pattern, with AIDS as the leading underlying cause of death and YPLL. The underlying causes of death in our cohort are, however, similar to those of the 1986–1987 San Francisco population for white men aged 25 to 44.[11]

Unlike mortality studies of HIV infection in intravenous drug users,[4] most underlying causes of death associated with HIV infection in this cohort met the AIDS case definition. For example, sepsis was reported to be a common cause of death in intravenous drug users who did not have AIDS,[4] but in our study sepsis was usually reported with AIDS. Excess rates of suicide, however, warrant further investigation.

AIDS surveillance provided more complete AIDS reporting than did death certificates, with 0.7% versus 9% underreporting. This low rate of underreporting (0.7%) is likely due to comprehensive case surveillance in San Francisco, which includes death certificate review for case identification.

Even in a San Francisco cohort of homosexual and bisexual men, AIDS is underreported as an underlying cause of death on death certificates. The omission of HIV infection or AIDS on the death certificates may be due to lack of knowledge about proper completion of death certificates, intentional cover-ups to protect patients' confidentiality, cause of death's being unrelated to HIV infection, or incomplete knowledge of the decedent's medical condition.

The impact of HIV infection and AIDS on premature mortality will continue to increase both in the cohort and in the United States. Because homosexual and bisexual men were among the first risk groups infected with HIV,[7] the patterns seen in the San Francisco City Clinic cohort may predict future patterns for the United States. National mortality trends have already changed, with HIV infection ranked sixth in 1989 for estimated YPLL among all persons dying before age 65.[12] In 1988, HIV infection/AIDS became the third leading cause of death among US men 25 to 44 years of age; it was estimated to be the second leading cause of death in 1989.[13] As HIV infection spreads into other transmission risk groups, such as intravenous drug users, their sex partners, and their children, AIDS and HIV infection will continue to be an important cause of morbidity and premature mortality in the United States. □

Seroprevalence of HIV-Type 1 in a Northern California Health Plan Population: An Unlinked Survey

Robert A. Hiatt, MD, PhD, Frank J. Capell, and Michael S. Ascher, MD

ABSTRACT

We conducted an unlinked seroprevalence survey for human immunodeficiency virus–type 1 (HIV-1) of 9821 persons who had a routine personal health appraisal examination in 1989 while members of the Kaiser Permanente Medical Care Program in northern California. An outside laboratory performed enzyme immunoassay (EIA) analyses, and the California Viral and Rickettsial Diseases Laboratory confirmed EIA-reactive samples by immunofluorescent assay and Western blot assay. Only 20 specimens (0.2%) were confirmed as positive, and 18 were from men. These data suggest that, at the time of this survey, HIV-1 infection was not widespread in the northern California population represented by this health plan membership. (*Am J Public Health.* 1992;82:564–567)

Introduction

Seroprevalence studies designed to assess the spread of human immunodeficiency virus–type 1 (HIV-1) infection in the general population are usually biased by the selected or voluntary nature of the sample or are limited in their generalizability because of the specialized nature of the survey population.[1–5] Unlinked (blinded) surveys bypass the need for informed consent and thus eliminate selection bias from this source.

We conducted an unlinked survey among nonhospitalized members of a large northern California prepaid health plan with characteristics representative of the general population in that region. The study protocol was approved by the Institutional Review Board of the Kaiser Permanente Medical Care Program (KPMCP), Northern California Region. We believe our results can be generalized to the symptom-free general population surrounding the city of San Francisco, one of the areas with the highest prevalence of HIV-1 in the United States.

Methods

Study Population

The KPMCP is a group-model, prepaid health maintenance organization that in 1989 provided comprehensive medical care to 2 190 629 members, or approximately 30% of the population in the counties of northern California where KPMCP provides services. The membership is comparable with the general population in terms of age and sex, and it includes the full spectrum of the region's racial, occupational, and socioeconomic groups.[6,7]

Data Collection

At most KPMCP facilities, members older than 15 years of age can voluntarily take a personal health appraisal (PHA) that includes a questionnaire, a physical examination, and laboratory tests. A PHA might be done because of a member's or provider's perceived need for a checkup, either to collect baseline data when the member first joins the health plan or starts with the new provider, or to provide a broadly based assessment for nonspecific complaints or concerns. It is generally not used as a diagnostic tool for focused complaints. Persons who take PHAs are likely to differ from the general plan membership; however, except in one facility,[7] this trend has not been systematically examined.

Aliquots of sera from 10 000 consecutive PHA samples drawn at nine Kaiser Foundation facilities (Figure 1) in October

Robert A. Hiatt is with the Division of Research, Kaiser Permanente Medical Care Program. Frank J. Capell is with the Office of AIDS and Michael S. Ascher is with the Viral and Rickettsial Disease Laboratory of the California Department of Health Services.

This paper was submitted to the Journal April 17, 1991, and accepted with revisions September 20, 1991.

and November of 1989 were coded and linked with KPMCP data on the member's 5-year age group, sex, zip code, date of PHA, and facility. The coded aliquots were sent on dry ice to an outside non-KPMCP laboratory (Alpha Therapeutics in Memphis, Tenn). All specimens were tested by enzyme immunoassay (EIA) (Pharmacia, ENI-Virgo), for which this laboratory is federally licensed, and positive specimens were retested. Specimens found by EIA to be positive for HIV-type 1 and an equal number of randomly selected negative specimens were sent to the Viral and Rickettsial Disease Laboratory of the California Department of Health Services in Berkeley, where repeat EIAs, Western blot assays, and immunofluorescent antibody testing were done. Codes for specimens testing positive by EIA, Western blot, and immunofluorescent antibody assay were reported as HIV-1 positive to the Department of Health Services' Office of AIDS, which also received coded demographic information from the KPMCP. It was not possible for any party in the study to trace a positive result to any individual.

Results

From the original dataset of 10 000 samples, 179 samples were eliminated because they were either found to have been duplications or drawn for specific laboratory tests rather than for PHAs. Age and sex distribution for the remaining 9821 samples was similar to that of all health plan members older than 15 years of age (Table 1). Twenty of the 9821 samples were confirmed as positive for HIV-type 1, for an overall prevalence of 0.2%. Eighteen of these were from men, and the age-specific prevalence was highest among those 20 to 29 years of age (Table 2). The distribution by facility or zip code grouped by major geographic area in northern California suggests that the prevalence of HIV-1 was slightly higher for persons living on the San Francisco peninsula and in the East Bay than for persons living in other areas served by the health plan, but numbers were small and 95% confidence intervals were wide.[8]

The San Francisco peninsula sample included 419 residents of San Francisco who obtained PHAs from the South San Francisco facility, but the sample did not include specimens from the San Francisco facility, which does not have a PHA program. Multiple logistic regression analyses for age, sex, and regions separately and together confirmed that the strongest determinant of HIV-1 positivity in this sample was being male and 20 to 29 years of age. No marked differences by region were found.

Discussion

Our study illustrates the usefulness of unlinked seroprevalence surveys in providing important public health information while protecting the confidentiality of the individual.[9–11] Such surveys are methodologically required in states such as California, where the results of individual HIV-1 testing are kept confidential by law, but they also have advantages in states without such laws, where any survey based on voluntary participation is likely to result in selection bias.[12] Considering that persons at high risk of HIV-1 infection

[a]For the expectation of a Poisson variable.

were not excluded from our study, a prevalence of 0.2% suggests that, by the end of 1989, HIV-1 had not spread to any substantial degree to members of this health plan population who were not at high risk.

Persons from San Francisco, who may have been at higher risk than those from other areas served by the health plan, were underrepresented in this survey because the San Francisco medical center did not have a PHA program. The survey should thus be viewed as reflecting levels of HIV-1 infection in a primarily urban area surrounding, but not including, San Francisco. Moreover, intravenous drug users are not likely to have been included in this survey. With these caveats in mind, we believe this sample still more closely represents the overall level of HIV-1 infection in the general population of the San Francisco Bay Area than have previous surveys.

Estimates of HIV-1 seroprevalence among heterosexuals have been derived mainly from surveys of high-risk or self-selected volunteers, such as blood donors,[13] military recruits,[1,14] active duty personnel,[2,15] prisoners,[3] outpatients or emergency patients,[16] and those from sexually transmitted disease clinics.[5] A blinded serosurvey of all 135 808 childbearing women in California during the third quarter of 1988 found 0.074% positive for HIV-1; 0.129% of San Francisco Bay Area childbearing women were positive[4] compared with 0.036% of the health plan women in our survey.

The closest comparison data to our survey are the results of the Centers for Disease Control's anonymous seroprevalence surveys at sentinel hospitals in the United States.[10] For eight hospitals in the West surveyed from January 1988 through June 1989, the overall prevalence was 0.35% (range: 0.1–0.7%). The peak prevalence was highest in the 25- to 34-year-old age group. Persons admitted for diagnoses often associated with HIV-1 infection were excluded.[17] Nevertheless, the sentinel hospitals' slightly higher overall prevalence of 0.35%, compared with a prevalence of 0.20% found by our survey, could be due to the higher probability of hospitalized patients being infected with HIV.

The results of our survey may be reassuring to persons concerned about the heterosexual spread of HIV-1 infection. At least in this northern California health plan population, levels of infection appear low. However, this does not minimize the need for educational efforts to optimize the practice of safe sexual behavior. The most conservative projections indicate that the number of persons with active HIV-1 infection will be substantial throughout at least the next decade,[18] and even a low level of risk for this uniformly fatal disease is important. □

The Validity of Self-reported HIV Antibody Test Results

Jane McCusker, MD, DrPH, Anne M. Stoddard, ScD, and Ellen McCarthy, MPH

ABSTRACT

Three hundred twenty-six participants in a multisite study were initially tested for human immunodeficiency virus (HIV) antibody and later interviewed; 228 were recent drug injectors and 38 were HIV positive. Later, 264 (81%) correctly reported their test results, 9 (3%) gave incorrect results, and 53 (16%) said either that they had not been tested or that they did not know the results. The predictive values of positive and negative self-reports were 90% and 98%, respectively ($P < .01$). (*Am J Public Health.* 1992;82:567–569)

Introduction

Research on the occurrence and correlates of human immunodeficiency virus type 1 (HIV-1, referred to in this paper as HIV) ideally is based on laboratory-confirmed antibody test results. In some situations, however, laboratory confirmation is not available—perhaps because of concern with confidentiality or inadequate resources to test all study subjects—and only self-reported results are available. The decision on whether to use these results rests on whether their inclusion will introduce bias. The inclusion of subjects who report inaccurate results would introduce information bias; their exclusion might introduce selection bias, for example, by excluding subjects who are not retested because they report a positive test result. In this study we investigated the validity of self-reported results among individuals who were initially tested in a multisite HIV surveillance project targeting intravenous drug users and their sexual partners,[1,2] and who were later reinterviewed regarding their test results.

Methods

Methods of enrollment and data collection have been reported previously.[2,3] Study participants included persons requesting HIV antibody testing at two city health department clinics, two community health centers, and a men's jail from September 1987 to December 1989, or at three drug abuse treatment programs during 1988 and 1989. Interview data were kept in client records at drug treatment sites. At other sites, interview data were used only by the HIV counselor and were stored confidentially. Participants were informed about these procedures. All testing was carried out in one laboratory: commercially available FDA-approved enzyme-linked immunosorbent assays (ELISA) kits, were used for initial serological screening and positives were confirmed with a Western blot test.

For this analysis, we examined the subset of participants who were reinterviewed during the study period. Reasons for reinterview included retesting at the same or another site and subsequent admission (or readmission) to one of the drug treatment programs. Self-reported results at the reinterview were compared with actual test results by HIV antibody status and other characteristics of the subjects. Differences in percentages were tested by the normal approximation to the binomial distribution, using a 5% level of statistical significance. Predictive values of positive and negative self-reports were computed.[4]

Results

A total of 2304 individuals were tested for HIV antibody, of whom 33% were recent needle users and 22% were tested while in drug abuse treatment. Of the 2304 tested, 326 (14%) were reinterviewed at the same or another study site

TABLE 1—Agreement between Actual and Self-reported HIV-1 Antibody Status, Stratified by Selected Variables

Variable	Total	Result Reported			Correct Result[b]		
		No.	%	P[a]	No.	%	P[a]
Actual HIV result							
Positive	38	33	87	.58	27	82	<.001
Negative	288	240	83		237	99	
Recent IVDU							
Yes	228	190	83	.82	182	96	.18
No	96	81	84		80	99	
Interval from test							
<6 Months	167	136	81	.25	132	97	.63
6+ Months	159	137	86		132	96	
Follow-up site							
Same	175	150	86	.29	149	99	.004
Different	150	122	81		114	93	
Treatment	206	167	81	.09	158	95	.02
Other	119	105	88		105	100	

[a]*P* values are based on normal approximation to the binomial distribution.
[b]The denominator is the number of those reporting a result.

during the study period. Those reinterviewed were significantly more likely to be recent needle users (70%) and to have been tested initially during drug abuse treatment (41%).

The HIV seroprevalence in the study group was 12% (38/326). At the second interview 21 subjects (6%) said they had not been tested before, 32 (10%) said they had been tested but did not know the result, and 273 (84%) reported at least one prior test result. In the latter group we tried to match the report to the index test by searching for the closest self-reported test date. Of the 221 subjects who gave a month and year, we found a report for the same month and year for 107, a report within 1 month for 54, and a report dated more than 1 month from that given for 60. Of the 39 who gave only a year, we found a report in the same year for 24 and a report in a different year for 15. The remaining 13 gave no test date.

The percentages of HIV-seropositive and -seronegative subjects who reported test results were similar (87% and 83%, respectively), but among those who reported results, seropositive subjects were significantly less likely than seronegative subjects to report their results correctly. Of 243 negative test reports, 6 were false negatives, whereas 3 of 30 positive reports were false positives, giving predictive values of 98% for a negative report and 90% for a positive report. We are confident that subjects were reporting the same result as the index test in all of the false-positive reports and all but one of the false-negative reports. (See Appendix A for details of these cases.)

The correspondence of reported with actual test results was stratified by several other variables (Table 1). The percentage of missing and unknown results did not differ significantly by recent intravenous drug use, interval between the two visits, whether the follow-up was at a drug abuse treatment site or another site, or whether the follow-up was at the same site as the initial visit. There was no significant association between accuracy of the reported result and recent intravenous drug use or interval between visits. Test results were more likely to be reported correctly if individuals were reinterviewed at the site where they had been tested and if this site was a non–treatment site. The sample was too small for us to determine whether these site effects were independent. Furthermore, for most of the subjects interviewed at a different site, this was a treatment site (88%).

Discussion

We found that HIV-seropositive persons were more likely to misreport their test results than were HIV-seronegative persons, particularly if they had been tested at a different site. We were not able to determine the reasons for this misreporting or whether it was intentional. During the study period, drug users who tested positive were given priority for admission into treatment, which might have accounted for the false-positive results. On the other hand, false-negative results might have been reported by individuals who wished their serostatus to be confidential for fear of stigmatization.

There was a strong trend for those who were followed up at the same site where they were tested to report their results more correctly, although this trend was of borderline statistical significance. This finding supports previous findings that intravenous drug users are more likely to provide correct information when they know that other sources of information exist.[5]

We acknowledge the limited generalizability of the results of this study, which was restricted to individuals who initially chose to be tested and were recontacted either because they wished to be retested or because they entered drug abuse treatment. However, these limitations apply to most research on self-reported HIV status among drug-using populations.

Previous research on drug users has generally found good agreement between self-reports and official records,[6,7] although this finding is not universal.[8] It is important to distinguish between inability to give correct information, owing to memory lapses or recent drug use, from unwillingness; social desirability and the perceived acceptability of the response can be powerful predictors of validity.[5]

The predictive value of test results is of interest to those deciding whether to include self-reported results in estimates of total seroprevalence. Our data suggest that the predictive values of both positive and negative self-reports were high, with positive self-reports somewhat less predictive than negative self-reports (90% vs 98%). Predictive values in other populations will vary with HIV seroprevalence.[4]

Given their generally high validity, it may be appropriate to use self-reported results in certain situations, for example, when a substantial proportion of the population does not have laboratory-confirmed results and where the costs of potentially redundant testing are prohibitive. In these situations, the selection bias introduced by exclusion of self-reported results may be greater than the information bias introduced by their inclusion. To minimize information bias, it would be important to assure clients in treatment programs that reporting would be confidential. Seroprevalence estimates that are based on self-reported test results may also need to be adjusted for

seroconversion, particularly if there has been a substantial lag since the most recent negative test. □

APPENDIX A—Further Details on the False-Positive and False-Negative Reports

False positives (n = 3). Two of these subjects reported having been tested in the same month and year as the index test. Both subjects were retested at the reporting visit, with another negative test result. The third subject reported only a year of testing (the same as the index test year) but reported three consecutive positive test results during that year. This subject was not retested and no validated reports of prior positive test results were obtained.

False negatives (n = 6). Four of these subjects reported a test date that was either the same as the index test date or more recent. The fifth subject reported two negative test results during the same year as the index test date, but gave no month. However, at a later interview, this person reported negative test results for the same year as well as for the following year. Inasmuch as documented cases of seroreversion from HIV seropositive to HIV seronegative are extremely rare, these cases in all probability reflect inaccurate reporting. The sixth subject reported a negative test result that was 2 years before the index positive result. We were not able to determine whether this reflected inaccurate reporting of the test result, or failure to report on the index test.

Cognitive and Attitudinal Impacts of a University AIDS Course: Interdisciplinary Education as a Public Health Intervention

Ronald P. Strauss, DMD, PhD, Inge B. Corless, RN, PhD, James W. Luckey, PhD, Charles M. van der Horst, MD, and Betty H. Dennis, PharmD, MS

ABSTRACT

This paper describes an interdisciplinary, variable credit-bearing university course on acquired immunodeficiency syndrome (AIDS) that enrolled 429 students. Pre- and post-course questionnaires were used to assess knowledge and attitudes relative to AIDS and these were compared to National Health Interview Survey findings. Considerable cognitive and attitudinal changes occurred over the course period. University courses, taught annually, were found to be an efficient mechanism for educating large numbers of future community leaders and professionals about AIDS. (*Am J Public Health.* 1992;82:569–572)

Introduction

The onset and spread of human immunodeficiency virus (HIV) infection has raised many social, ethical, and clinical issues that are of importance to individuals from varied backgrounds. A university course that provides a detailed education about HIV infection and acquired immunodeficiency syndrome (AIDS) serves to develop expertise in future community and professional leaders, and may enlighten society's response to this health care and social crisis. The educational topics incorporated in a disease-specific educational offering are applicable beyond the focus on AIDS. AIDS was dealt with in this course not only as a disease, but also as a case study of how societies deal with contagion, stigma, disability, death, social stratification, and access to scarce resources.

[a]Health Information Survey data from 1989 provisional estimates, January to March 1989.

Universities in the United States have responded to AIDS by incorporating relevant information into courses currently offered to students and by developing new courses.[1–4] Cross-sectional surveys and other reports have defined gaps in HIV-related knowledge and attitudes among college students.[5–27] However, the literature on the impact of AIDS education suggests that knowledge and attitude changes do occur over the course of educational programs.[1–3,28–31]

This paper describes a study of an AIDS course as a public health intervention and examines cognitive and attitudinal changes that occurred in students over the course period.

The course, "AIDS: Principles, Practices and Politics," combined faculty and resources from health and social science disciplines. One faculty member from the Schools of Dentistry, Medicine, Nursing, Pharmacy, and Public Health participated in organizing and teaching the course, thus exemplifying the interdisciplinary approach necessary to provide care and resolve the AIDS crisis.

Students, who were drawn from every school on the university campus, included undergraduates (69%), professional/graduate students (28%), and others (3%). Offered at one to three credit levels, the course involved weekly lectures, readings, and a graduate seminar. Enrollment between 1989 and 1992 has varied from 250 to 550 students per semester, with 429 enrolled in 1989.

Methods

In 1989, an anonymous precourse questionnaire was administered to students to examine their risk factors, knowledge, and attitudes. Three hundred and thirty-nine students took the pretest, and their responses were compared with those of the 245 students who took the posttest. The data were treated in the aggregate, as the anonymity of the instrument precluded matching individual precourse and postcourse questionnaires. Some of the questions were drawn from the National Health Interview Survey (NHIS),[32] and findings include comparisons with these national data. Postcourse test mean responses were compared with precourse means using *t* tests and chi-square.

Results

Student knowledge about the risk factors for infection with the AIDS virus are displayed in Table 1. When compared with national surveys of US persons aged 18 to 29, from the same time period (NHIS, January to March 1989),[32] it is evident that our sample of university students was less concerned about casual HIV transmission.

Students starting this course were more educated and accurate about risk factors for HIV infection than those in the national sample. Though students expressed no concern about living near, shaking hands with, touching, kissing on the cheek, or attending school with persons infected with the AIDS virus, the precourse survey showed some concern about other forms of casual contagion. These included sharing eating utensils (7%), eating in a restaurant where the cook has the virus (6%), and being coughed or sneezed on by an infected person (8%). There was also some concern about mosquitoes and other insects (10%). The relatively low level of precourse concern or misinformation was reduced during the course.

Should health insurance companies be allowed to ask questions to determine if someone belongs to a high-risk group for AIDS before issuing a policy?	47.0	(157)	36.4	(87)	6.407	.011*
Should insurance companies be allowed to exclude coverage specifically for conditions resulting from the AIDS virus?	15.0	(50)	4.2	(10)	17.635	.000***

Note. *df* = degrees of freedom.
* = $P < .05$, ** = $P < .01$, *** = $P < .001$.

At the start of the course, 18% of the students indicated that their blood had been tested for HIV (Table 2); this was less than NHIS cohort findings (26% among 18- to 29-year-olds). Over the period of the course, an additional 5% were tested. Most students reported that HIV testing had occurred through a blood donation, with fewer than a third specifically seeking a blood test voluntarily. When presented with a list of risk factors before the course, 6% of the students identified themselves as members of a high-risk group. This was twice the rate reported for the 18- to 29-year-old cohort in the NHIS. At the end of the course, an additional 3% (amounting to a postcourse total of 9.5%) rated themselves as having behaviors that might place them at risk for HIV infection.

Attitudes toward the rights of health workers to refuse to care for persons infected with HIV changed over the course period (Table 3). There was a significant reduction in the percentage of those who indicated that physicians (–13.7%) and nurses (–13.5%) had such a right. Attitude changes were found, demonstrating by the course end increased understanding and tolerance for persons who are HIV positive.

Anonymous course evaluation forms were distributed after the final class sessions. Students largely rated the course and the lectures as good or excellent. The class most highly ranked was "The Human Side of AIDS," a panel of persons with AIDS. Ninety-five percent of the students would have recommended the course to others.

Discussion

This initiative in university interdisciplinary course development shows that large numbers of university students will

enroll in a credit-bearing course on AIDS. Variable-credit course options will attract undergraduate lecture course students as well as graduate seminar students.

This project indicates that many and significant changes occur in student knowledge and attitudes about AIDS over the period of a university course on AIDS. It suggests that other universities might use this interdisciplinary educational approach and public health initiative to educate students—our future community leaders and professionals—about AIDS. Health sciences professional schools are in a unique position to begin similar campuswide educational programs that demonstrate in education the interdisciplinary nature of the work required in practice. □

Acknowledgments

This research and educational initiative was supported by a grant from the Pew–Rockefeller Health of the Public Program, the UNC Center for Health Promotion and Disease Prevention. This paper was presented in part at the Sixth International Conference on AIDS on June 21, 1990, in San Francisco, CA. It was also partially included in a presentation at the annual meeting of the Association of American Medical Colleges on October 21, 1990, in San Francisco.

Special appreciation goes to Dr. H. Garland Hershey (vice chancellor of Health Affairs and vice provost, University of North Carolina at Chapel Hill) and the Lupton Opportunity Fund for their support of this project.

Ineffectiveness of AIDS Education and HIV Antibody Testing in Reducing High-Risk Behaviors among Injection Drug Users

Donald A. Calsyn, PhD, Andrew J. Saxon, MD, George Freeman, Jr, MA, and Stephen Whittaker, ARNP

ABSTRACT

The effectiveness of education in reducing high-risk human immunodeficiency virus (HIV) transmission behaviors was examined in 313 injection drug users. Involvement in high-risk behaviors was assessed via structured interview at study entry and 4 months following the intervention. Subjects were randomly assigned to (1) AIDS education, (2) AIDS education with optional HIV antibody testing, or (3) a wait list. The sample as a whole decreased its involvement in high-risk behaviors, but there were no significant differences as a function of experimental group assignment. (*Am J Public Health.* 1992;82:573–575)

Introduction

Several reports indicate that injection drug users (IDUs) are decreasing their sharing of injection equipment and increasing their use of bleach to clean shared equipment.[1–3] Smaller decreases in high-risk sexual behaviors by IDUs have been found by some but not all investigators.[4] The primary acquired immunodeficiency syndrome (AIDS) prevention tools used to date with IDUs have included mass media education, street outreach education (often involving the provision of bleach and free condoms), human immunodeficiency virus (HIV) antibody testing and counseling, and educational programs for targeted subgroups. Although reductions in risk behaviors are often attributed to these educational and exhortative efforts,[3] no research using randomly assigned control groups has demonstrated the efficacy of specific educational prevention interventions.

The research reported here tested the hypothesis that a 90-minute AIDS education package and knowledge of one's HIV status will reduce high-risk behaviors among IDUs in treatment. A 90-minute educational format was chosen because it seems typical of interventions provided by drug abuse treatment programs with limited resources.

Methods

Three hundred thirteen IDUs receiving or seeking treatment in Seattle, Wash, served as subjects. The subjects were recruited from Evergreen Treatment Services, a nonprofit methadone maintenance program, and the Addictions Treatment Center of the Veterans Affairs Medical Center. The subjects volunteered to participate in an AIDS prevention project and gave informed written consent. They received $30 to defray expenses for each interview. The subjects were representative of clients in treatment in these settings with respect to demographics and involvement in high-risk behaviors.[5]

At enrollment into the project, all subjects were assessed via a structured interview regarding high-risk behaviors.[5] Immediately following this initial interview, all subjects were randomly assigned to one of three AIDS prevention intervention conditions: (1) a 90-minute group AIDS education session, (2) the AIDS education session plus optional HIV antibody testing, or (3) a 4-month wait list.

The AIDS education sessions were conducted by two trained facilitators who lectured from a scripted format while also responding to questions and allowing discussion. The format covered considerable information about the transmission of HIV, the medical aspects of AIDS, HIV antibody testing, and a three-tiered risk reduction strategy: (1) abstinence from illicit drug use, especially injectables, and celibacy; (2) no sharing of injection equipment and long-term monogamy with a known low-risk partner; (3) cleaning of injection equipment with bleach and use of condoms for all sexual activity. A highly emotional videotape, *Drugs and AIDS: An Appeal to Users*,[6] featuring a recovering addict reinforcing the risk reduction strategy, was shown. Cleaning of a syringe with bleach and application of a condom to a dildo were demonstrated. Small vials containing bleach and a starter pack of condoms were given out at the completion of the session.

Four months after the intervention, all subjects who could be located (n = 218) were assessed for behavioral changes in a

structured interview similar to the initial interview. The interviewers were blinded to the subjects' educational group assignments. All outcome measures of interest were dichotomized. Changes from initial to follow-up assessment were analyzed by means of the McNemar statistic.

Results

Table 1 contains demographic data for the entire sample and comparisons of follow-up completers and noncompleters. As one might anticipate, completers were more stable than noncompleters. The sample was knowledgeable about AIDS transmission at entry. In response to the open-ended question "What do you know about how people get AIDS?" 90.1% spontaneously mentioned needle sharing and 69.6% mentioned heterosexual activity. To true-false questions concerning means of contracting AIDS, 99% correctly identified needle sharing, 98.7% indicated sexual activity, and 96.8% knew that condoms could reduce risk.

Only 3 subjects (1.4%) of the 213 tested were HIV seropositive.

Table 2 presents the needle-use and sexual risk variables for the sample, initially and at follow-up. On all needle-use variables, significant improvement occurred. Both men and women reduced their numbers of sexual partners; an increase in condom use occurred only for males with multiple partners. No significant differences existed among the three experimental groups on any demographic or high-risk behavior variables at initial assessment. Nor were differences found among experimental groups on any outcome measures.

Discussion

Like other investigators, we observed that IDUs, as a group, were reducing their involvement in high-risk behav-

iors. Nonetheless, in contradiction to our original hypothesis, we found no differential benefit from a 90-minute AIDS education program with a random-assignment control-group design. Our results accord with those of Gibson et al.[7] and McCusker et al.,[8] who found no differences between experimental educational and minimal control-group interventions when random assignment designs were used.

We feel the failure of the interventions probably reflects their essential misdirection. They were designed primarily to provide information, under the assumption that the subjects had little knowledge about AIDS. In fact, the subjects demonstrated remarkably good knowledge prior to the interventions.

Other factors that may have contributed to the absence of educational effects include the following: (1) The generally low rate of needle sharing in this sample[5,9,10] may have provided a basement effect for the number of needle-sharing partners variable. (2) Informal communication about the education between subjects in the education and wait list conditions could have confounded the intervention. Magura et al.[11] demonstrated that peer influences were the most salient predictors of needle sharing. (3) Public service education and outreach campaigns in progress at the time of the study could have imparted to wait-list subjects information similar to that provided in the intervention. (4) The initial assessment interview may have served as a positive intervention by heightening subject awareness in an already knowledgeable group.

Despite these potential confounders, our results call into question the extensive expenditure of resources on AIDS education that is primarily information-giving in nature with already knowledgeable populations. Future investigations should explore alternative interventions that might be more effective.

The lack of differential behavior change in the subjects receiving HIV testing compared to those not tested may be related to the seronegative status of the vast majority tested. Previous research suggests that persons who are seropositive, but not those who are seronegative, change their behavior after learning their status.[12,13] Our findings suggest that HIV testing in low endemic areas is unlikely to result in reductions in high-risk behaviors among IDUs. This implication does not diminish the importance of HIV testing programs in these areas for seroprevalence monitoring and early medical intervention with persons found to be seropositive. □

Duration of Medicaid AIDS Hospitalizations—Variation by Season, Stage, and Year

Leona Enama Markson, ScD, Barbara J. Turner, MD, MSEd, and Thomas R. Fanning, PhD

ABSTRACT

Using New York State Medicaid data from 1984 to 1987, we analyzed hospital length-of-stay patterns for acquired immunodeficiency syndrome (AIDS) patients. We found an overall decline in monthly average length of stay, with seasonal fluctuations producing longer stays in the fall and winter months. These findings suggest that hospital utilization for AIDS patients is changing over time and may vary by season. (*Am J Public Health.* 1992;82:578–580)

Introduction

Over the past decade, hospitals in several regions of the country have been heavily burdened by the dramatic rise in the number of acquired immunodeficiency syndrome (AIDS) patients.[1,2] Inpatient care is one of the most expensive components of the cost of AIDS,[3–5] and hospitals in New York State have one of the longest average lengths of stay for AIDS care in the country.[2,6,7] Information on patterns of AIDS hospitalizations is needed to assist hospital planners in meeting the needs of this special population. In this study, we analyzed length-of-stay patterns for New York State Medicaid AIDS hospitalizations to examine temporal patterns and changes in hospital length of stay.

Methods

We examined hospital claims for New York State Medicaid AIDS cases over 35 months, from October 1984 through August 1987. Using a methodology tested elsewhere,[8] we identified a hospital stay as an AIDS admission if one of the following ICD-9-CM codes was recorded: *Pneumocystis carinii* pneumonia (136.3), selected immunodeficiency codes (279.10 and 279.19), or the AIDS codes (042.xx or 043.xx).

The study population comprised AIDS patients aged 15 to 65 years who were hospitalized for nonobstetric reasons. Two classes of outliers were deleted from the sample: patient admissions with stays of more than 66 days (less than 5% of the patients) and those with more than eight inpatient stays over the 35-month period (1.5% of the patients). The study sample consisted of 11 482 patient admissions; males constituted approximately three fourths of the sample. Eighty-two percent of the sample was 26 to 45 years of age at the time of hospitalization.

To adjust for differences in case mix, we determined the severity of each case, using the Staging Classification for AIDS Hospitalizations.[9,10] This AIDS staging system can be summarized into three integer stages, with stage 3 indicating the most severe cases. Stage 4 is used in some analyses to distinguish patients who died in the hospital.

Length of stay was analyzed as an average per month, calculated as the av-

erage length of a hospital stay for all patients admitted in the same calendar month. We observed patterns in length of stay by plotting 3-month moving averages, a useful smoothing technique to reduce the short-term fluctuations in time-series data.[11] To compute 3-month moving averages, we determined the average length of stay for all patients admitted from October 1984 through December 1984, then determined the 3-month average for November 1984 through January 1985, and so on. Moving averages were used only in plotting to assist in visual analysis of trends.

To assess the influence of stage, year, and season, we used multiple linear regression to model monthly variation in hospital stays across the total population. The sample size for this analysis equaled 140 "stage-months" of observation (35 months of utilization and discharge data, classified into four stages). For example, the average length of stay for all Stage 1 patients admitted in the first month of the study is one of the 140 observations. Natural logarithms were used to transform average length of stay per month to produce a more normal distribution of the dependent variable.

Results

Figure 1 displays two trends in monthly average length of stay for New York Medicaid AIDS cases: (1) an overall downward trend ($r = -.62$, $P < .001$) and (2) a periodic trend, with longer stays in the fall and winter months. The longest average length of stay was 21.2 days, in October 1984 (month 1 of the study); the shortest was 13.8 days, in August 1987 (month 35). For each of the federal fiscal years (FFYs) of the study, the average length of stay for the month of January was compared with the average length of stay for the month of June; length of stay was longer in January by 2.8 days in FFY 1985, 1.1 days in FFY 1986, and 2.4 days in FFY 1987. The periodic trend in monthly average length of stay remained after patients who died in the hospital were removed from the analysis.

Overall, the average length of stay was 13.0, 19.2, and 20.3 days for patients in stages 1, 2, and 3, respectively. Average length of stay by fiscal year was 17.5 days in FFY 1985, 16.4 days in FFY 1986, and 15.9 days in FFY 1987. The regression analyses shown in Table 1 indicate that stage, year, and season explained 76% of the variance in monthly length-of-stay patterns ($F = 50.5$, $P < .001$). Cases classified in stages 2 and 3 had stays that were 58% longer than the stays of cases in stage 1 ($P < .001$), and hospital stays were on average 7% longer ($P < .05$) in fall and winter months than in summer months. After adjustments were made for stage and fiscal year, hospital stays declined by approximately 6% in FFY 1986 and 11% in FFY 1987 as compared with FFY 1985 ($P < .001$). These numbers represent approximately a 1-day decline in hospital length of stay per year.

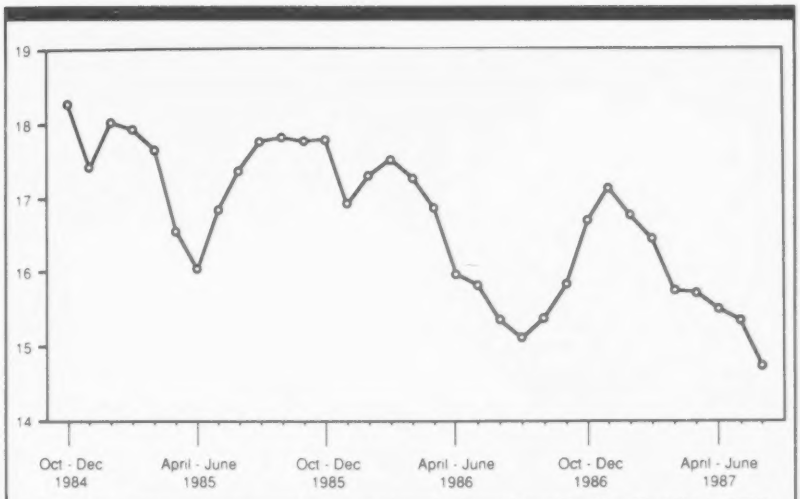

FIGURE 1—Three-month moving average length of stay (days) for New York State AIDS patient admissions from October 1984 through August 1987.

Discussion

Our analyses indicate that length of hospital stay for Medicaid AIDS patients in New York State has declined in recent years, but that average length of stay per month varies depending upon the season of the year and the case mix of the population. Although the effect of season was not large after adjustments were made for severity of illness, seasonal variation in hospital utilization for AIDS patients needs to be explored further. AIDS patients are susceptible to conditions such as respiratory infections, for which prevalence rates and case fatality rates are known to peak in the winter months.[12–14] Other explanations, independent of clinical issues such as availability of nursing home beds, may contribute to seasonal fluctuations in the demand for hospital care. There have been reports on seasonal variations in hospital crowding in New York City in recent times,[15] and the influence of AIDS care in these seasonal hospital occupancy problems should be explored.

This study does not address reasons for the declining length of stay; however, the trend probably reflects improvements in clinical diagnosis and treatments, as well as improved outpatient care. A similar decline in length of hospital stay for a sample of AIDS patients in Massachusetts was recently reported.[16] In addition, data from the National Hospital Discharge Survey for all types of hospitalized patients discharged from short-stay hospitals in the United States indicate an overall decline in recent years in the average length of stay.[17] This national downward trend in length of stay across all diagnosis groups, which is often attributed to prospective payment systems, may also influence the hospital stay patterns for AIDS cases. However, per-case payment for New York Medicaid hospitalizations was not instituted until 1988, after the time of the study.

It should be noted that the observed decline in length-of-stay patterns may not be uniform across all hospitals in New York State. Our analysis focused on monthly variation in length-of-stay patterns and not on length-of-stay patterns within individual hospitals. In addition, our sample was restricted to Medicaid AIDS patients, and it is not clear whether these trends hold for patients not covered by Medicaid. In recent studies of hospital services for AIDS patients, Medicaid was found to be the most frequent payer of AIDS inpatient care.[16,18] Moreover, the number of AIDS patients enrolled in Medicaid is on the rise.[19–21]. As a result, patterns of inpatient care for Medicaid AIDS

TABLE 1—Regression Model of Monthly Log Average Length of Stay (October 1984 through August 1987)

Variable	Coefficient	Standard Error	*P* Value
Stage 2	0.46	.028	<.001
Stage 3	0.46	.028	<.001
Stage 4	0.40	.028	<.001

Decline in Human Immunodeficiency Virus Seropositivity and Seroconversion in US Navy Enlisted Personnel: 1986 to 1989

Frank C. Garland, PhD, Edward D. Gorham, MPH, Steven O. Cunnion, CAPT, MC, USN, Milan R. Miller, Louis L. Balazs, MS, and the Navy HIV Working Group

ABSTRACT

The US Navy administered 1 795 578 enzyme-linked immunosorbent assay (ELISA) tests to 848 632 active-duty Navy enlisted personnel during 1986 to 1989. This study identified 2438 human immunodeficiency virus (HIV)-seropositive active-duty enlisted Navy personnel, including 778 seroconverters. Three types of quarterly rates of HIV seropositivity and seroconversion were determined. All three rates declined. This decline could not be explained by changes in the population tested according to age, race, sex, occupation, or geographic location of home port. (*Am J Public Health.* 1992;82:581–584)

Introduction

The course of the human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome epidemic has been reported in various populations, including homosexual and bisexual men,[1–5] prisoners,[6–8] and military recruits.[9–11] This study reports quarterly time-trends in HIV seropositivity and seroconversion rates among active-duty enlisted US Navy personnel.

HIV seroconversion rates were previously reported for 1986 to 1988 for the Navy (0.70 per 1000 person-years) and Marine Corps (0.27 per 1000 person-years).[12] Army rates (0.77 per 1000 person-years)[13] were similar to those reported for the Navy.

Methods

The Naval Health Research Center in San Diego, Calif, maintains computerized career records for all Navy personnel and HIV testing histories for all those receiving enzyme-linked immunosorbent assay (ELISA) and Western blot tests. Many individuals had several tests during 1986 to 1989 as a result of routine screening and testing of personnel deployable overseas or health care providers.[12] Retesting allowed identification of seroconverters (i.e., persons with an initial negative test followed by a positive test).

All seropositive individuals had two positive paired ELISA tests (from the same blood collection) followed by at least one positive Western blot assay. The criterion for a positive Western blot assay was a specimen exhibiting at least two of three bands at p24, gp41, or gp120/160.[12] Sources of data and testing procedures have been described in detail elsewhere.[12]

For completeness in assessing trends, three rates were calculated: (1) the rate of newly identified HIV-seropositive individuals per 1000 tested, (2) the rate of HIV seroconversion per 1000 individuals tested with a previous negative test, and (3) the rate of HIV seroconversion per 1000 person-years. Person-years were computed as the time between an individual's first negative test and his or her first positive or last negative test. Persons with two negative tests were assumed to be negative through the end of the study period.

Crude rates based on person-years were dependent upon the number of tests administered during an interval, which varied among quarters. Therefore, these rates were adjusted for the number of tests per quarter.[14] Indirect age-adjustment (using age-specific Navy rates for the entire study period as the standard) was performed for the rate of HIV seroconversion per 1000 individuals tested with a previous negative test.[15] To determine if the population tested varied over time by age, race, sex, occupation, or geographic location, the percentage distribution of each of these factors by quarter was determined.

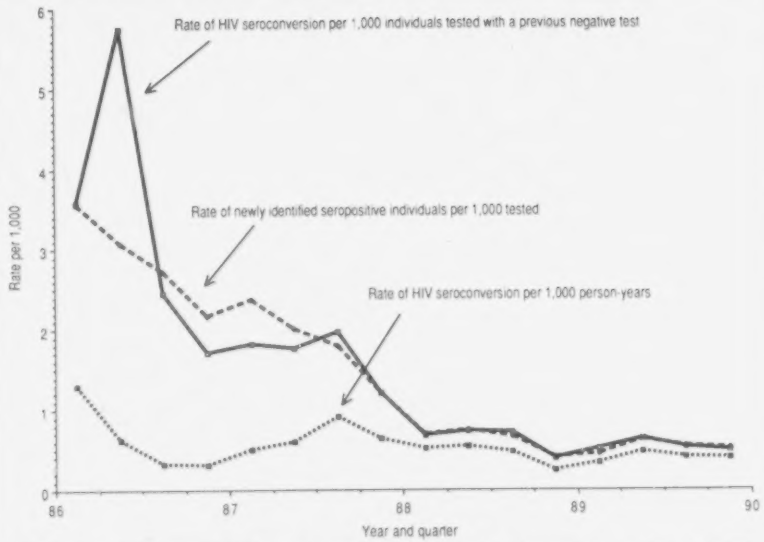

FIGURE 1—HIV seropositive and seroconversion rates, by quarter, active-duty US Navy enlisted personnel, 1986–1989.

Results

A total of 1 795 578 ELISA tests were administered to 848 632 individuals (mean number of tests per quarter, 112 224), and 2438 HIV-seropositive individuals were identified, of which 778 were seroconverters. Ninety-nine percent of the active-duty Navy enlisted population received ELISA tests during the study period.

The rate of newly identified seropositive individuals per 1000 tested declined from 3.6 in the first quarter of 1986 to 0.5 in the last quarter of 1989 ($P < .05$) (Figure 1). The mean annual rate declined from 2.9 in 1986 to 0.5 in 1989 ($P < .05$) (Table 1).

The rate of HIV seroconversion per 1000 individuals tested with a previous negative test peaked at 5.7 during the second quarter of 1986, then declined to 2.5 in the next quarter, a nonsignificant difference (Figure 1). The rates plateaued until the third quarter of 1987. This was followed by a decrease to a relatively stable level throughout 1988 and 1989, reaching 0.5 per 1000 in the fourth quarter of 1989, a lower HIV seroconversion rate ($P < .05$) than all quarterly rates in 1986 and 1987. The mean annual rate of HIV seroconversion per 1000 individuals tested with a previous negative test declined from 3.4 in 1986 to 0.5 in 1989 ($P < .05$) (Table 1).

There was little quarterly variation in the rate of HIV seroconversion per 1000 person-years (Figure 1). The mean annual rate in 1986, 0.9 per 1000 person-years, was more than two times higher ($P < .05$) than the mean annual rate of 0.4 in 1989 (Table 1).

The mean annual rate of HIV seroconversion per 1000 individuals tested with a previous negative test was higher for Blacks than for Whites in all 4 years ($P < .05$) (Figure 2). Seroconversion rates in individuals other than White or Black (i.e., Oriental, Filipino, and American Indian) were similar to those of Blacks in the first quarter of the study, but approximated those of Whites thereafter. A steep decline in rates occurred in persons 30 years of age or older between the first and third quarters of 1986 (Figure 3).

The proportion of the population tested by race, sex, and occupational risk group was similar in each quarter (not shown). There were some minor differences according to age.

Discussion

HIV seropositivity and seroconversion rates declined in the Navy during 1986 to 1989. The rate of newly identified seropositive individuals per 1000 tested and the rate of seroconversion per 1000 individuals tested with a previous negative test showed a more marked decline than did the rate of HIV seroconversion per 1000 person-years. The declining pattern in quarterly rates suggests the tail of an epidemic curve,[16,17] which may have peaked in or prior to 1986. The declining trend in the Navy was similar to that reported for the Army[18] and was consistent with the decline in seroprevalence rates observed in military recruits during 1985 to 1989.[11] Rates were markedly higher in Blacks than in Whites and other races in the early study period, which was also consistent with previous reports.[10,12,13]

The absence of a strong trend in the rate of HIV seroconversion per 1000 person-years may be partly explained by the method of calculation, which tended to reduce differences between quarterly rates. Nearly the entire population con-

tributed to each quarterly interval, whether or not the individuals were tested in a particular quarter.

The decline in rates was unlikely to be due to a change in the population tested over time, inasmuch as the population tested did not vary importantly by race, sex, or occupational risk group in each quarter. New York, San Francisco, and Washington, DC, were high-risk areas for HIV seropositivity in military recruits,[9] but the proportion of the population tested from these areas was not overrepresented during the periods of peaks in HIV rates.

There is currently no detailed information regarding trends in the Navy in behavior such as high-risk sexual activities and intravenous drug use, so the reasons for the decrease in HIV rates in the Navy are speculative. National educational campaigns and Navy-sponsored educational programs[19] may have succeeded in reducing some high-risk behavior. To the extent that HIV transmission occurs among active-duty Navy personnel, policies of exclusion of seropositive applicants and testing of active-duty personnel may have decreased the population of HIV carriers (and perhaps seronegative personnel with high-risk behaviors), leading to a reduction in the likelihood of HIV transmission within the Navy.

Most other studies of trends have been limited to high-risk groups,[1–8,20–22] which are presumably different from the Navy population in prevalence of risk factors. Several cautions must be considered regarding the generalization of the trends found in the Navy to other populations. The Navy is not representative of the greater US population in many respects, including its age and sex structure, and it specifically prohibits high-risk behavior.[23–26] The decline reported here in HIV seropositivity rates is encouraging, but may in part reflect a pattern imposed on the Navy population by testing and exclusion of HIV seropositive applicants. □

Fear of Dying and HIV Infection vs Hepatitis B Infection

Lawrence J. Schneiderman, MD, and Robert M. Kaplan, PhD

ABSTRACT

Accidental exposure to the blood of hepatitis B patients produced less fear than does accidental exposure today to the human immunodeficiency virus (HIV), even though both have an approximately equal overall risk of death (~1%).

Subjects responding to hypothetical insect-exposure and disease-exposure scenarios chose to avoid the HIV-type risk of 1% chance of exposure/100% chance of death.

Fear of certain death seems to account for the greater concern about exposure to HIV than to Hepatitis B. (*Am J Public Health.* 1992;82:584–586)

Introduction

Health care providers are at risk of infection resulting from accidental exposure to blood, such as needlestick injury. For many years before a vaccine became available, providers risked infection and death from hepatitis B. These risks were faced without the outcry and debate and the disruption of services that now attend the acquired immunodeficiency syndrome (AIDS) crisis. One of us, in a lecture to health care providers, pointed out this apparent irrationality of health providers' behavior in response to human immunodeficiency virus (HIV). As can be demonstrated by simple calculations, the probability of death from accidental exposure to HIV is no worse than was the probability of death from accidental exposure to hepatitis B in the recent past. The chance of hepatitis B infection following accidental exposure is in the range of 25%; we conservatively assume that about 5% of those infected die either from fulminant or chronic progressive disease.[1,2] The chance of HIV infection following accidental exposure is much lower, apparently no greater than 1%, and it is presently assumed that 100% of patients who are HIV infected will develop AIDS and its complications and die.[3]

Multiplying the probabilities of risk of infection following exposure by the risk of death following infection yields approximately equal outcomes. That is, in both circumstances there is an approximately 1% chance of dying following accidental exposure. Why then are health providers, who took relatively few precautions in the hepatitis B era, now taking exceptional precautions, some of them even refusing

to care for patients who are HIV infected? Are they sharing in society's "AIDS hysteria," much of which is known to be fanned by prejudice and ignorance? A member of the audience provided a thought-provoking answer: "The problem is that once you have HIV infection you have no chance. You know you're going to die." The answer suggested that even though the probability of infection is very low, the certainty of death might be so undesirable that it might account for the greater concern about HIV than about hepatitis B—a hypothesis we chose to test in an empirical study.

Expected utility theory[4,5] has traditionally served to explain decision-making processes that involve risk. According to this theory, individuals should favor the alternative that maximizes gains and minimizes losses. In the case of HIV and hepatitis B exposure, the expected utility of either alternative is nearly equal. Thus, it would be expected that the motivation to avoid each condition is approximately equal.

An alternative to expected utility theory was introduced more recently. This theory, known as prospect theory,[6] places greater emphasis on context effects. The theory suggests that a choice involving risk is strongly influenced by other contextual information. Unlike expected utility theory, prospect theory suggests that individuals do not take a comprehensive view of all possible outcomes that might be associated with a particular choice. Instead, they view the consequences of a particular choice as a change, which is judged as a gain or loss rather than the summation or final state of all possible outcomes. According to this theory, high probabilities of loss, such as certain death, might overcome low probabilities of the situation developing. Thus, prospect theory might suggest that fear of HIV should exceed fear of hepatitis B.

Methods

Subjects

The subjects were 264 undergraduate students at the University of California, San Diego, and San Diego State University. The students were enrolled in lower division courses in psychology and health sciences. These courses had not, at the time of the study, considered the AIDS epidemic. Sixty-one percent of the subjects were female and 39% were male. The mean age of the participants was 20.30 years (SD = 3.87 years).

TABLE 1—Comparison of Responses across Three Scenarios

Scenario	Total No. of Respondents	No. of Respondents Avoiding First Option	%
Disease (chance of infection following exposure × chance of death following infection)			
HIV (1% × 100%) vs hepatitis B (25% × 5%)	83	56	67
Insect (chance of being stung × chance of death after being stung)			
(1% × 100%) vs (25% × 5%)	91	58	64
(100% × 1%) vs (5% × 25%)	90	28	31

Note. HIV = human immunodeficiency virus. The disease scenario describes hypothetical HIV vs hepatitis B exposure. The insect scenarios compare hypothetical insect exposures.

Questionnaire

Each subject responded to one of three versions of a questionnaire. The first version described a situation explicitly specifying hypothetical hepatitis B and HIV exposures. Group 1 received a questionnaire that stated:

> Two diseases which can be acquired by accidental needlestick exposure to an infected patient are hepatitis B and AIDS. The risks of contracting hepatitis B from a needlestick are approximately 25%, and if one gets the disease there is approximately a 5% chance of dying. The risks of contracting AIDS from a needlestick exposure to an infected patient are approximately 1%, but 100% of those infected will die. Assume that a preventive vaccine is available for both diseases. You are a health care worker in a foreign country in which the prevalence of both diseases appears to be equal, but which can afford only one or the other vaccine for you. Which vaccine would you choose?

The subject could choose a hepatitis B or an AIDS vaccine.

The second and third groups were presented scenarios with similar contrasts in risks as in the first group, but in describing the hypothetical situations the scenarios eliminated the words *AIDS* and *hepatitis B*. The first of these conditions stated:

> You have been shipwrecked on the shore of a tropical country. The only passage to safety is by one of two routes, both of which expose you to insects of varying population intensity and lethality. Route A sends you to a valley where your likelihood of being stung is 25%. The chance of dying if you are stung is 5%. Route B sends you through a valley in which the insects are sparser but more lethal. Through this route you have a 1% chance of being stung, but if you are stung you are 100% certain to die. Which route would you choose?

The third set of scenarios (given to Group 3) was identical to the set given to the second group, except the probabilities of being stung and dying were reversed. Route A involved a 100% chance of being stung but a 1% chance of dying, while Route B involved a 5% chance of being stung and a 25% chance of dying.

Statistical Methods

Comparisons between conditions were achieved using χ^2 tests. *T* tests and χ^2 tests were used to evaluate the relationships between choice and demographic variables.

Results

Table 1 summarizes the choices for the three groups. Each choice was conceptualized as either avoiding HIV or avoiding hepatitis B risk situations. Because of the wording of the scenarios, this risk component was systematically varied across groups. In the insect scenario, 64% chose the route that avoided the 1% chance exposure and 100% death; in the explicit HIV–hepatitis B scenario, 67% preferred an AIDS over a hepatitis B vaccine. The difference between these two groups was nonsignificant ($\chi^2 = 0.26$).

When the probabilities in the insect scenarios were reversed (100% chance of being infected, 1% chance of dying; 5% chance of being infected, 25% chance of dying), the results changed. Under these circumstances, only 31% preferred the route with the 100% chance of being infected and 1% chance of dying. The difference between these two insect scenar-

ios (i.e., reversing the chances of being stung and dying) was statistically significant ($\chi^2 = 19.31, P < .001$). The subjects' response to the insect scenario with the reversed probabilities was also significantly different from the response to the explicit HIV–hepatitis B scenario ($\chi^2 = 22.85, P < .001$).

Age and sex did not significantly influence choice, as evaluated respectively by t tests (age) and χ^2 tests (sex). For example, in Group 2, 69% of the women and 66% of the men selected Choice 1. The mean age of those selecting Choice 1 was 21.61 years, while the mean age of those selecting Choice 2 was 20.34 years ($t_{89} = 1.33$, NS).

Discussion

Expected utility theory suggests that decisions should be based on the product of outcome and expectancy.[4,5] In this experiment we created scenarios in which the expected utilities of two outcomes were nearly equivalent. In all scenarios the subjects avoided outcomes that had a low probability of certain death. In the one condition that did not include certain death, subjects preferred the choice that offered the lowest probability of death. The effect of context observed in this study lends support to prospect theory.[6] In comparison to expected utility theory, prospect theory is better able to account for the effects of certain outcomes upon judgment.

Since responses to the insect scenarios and the identified disease scenario were not significantly different, data from this study may explain the differential attention to hepatitis B and HIV by health care providers. If fear of AIDS caused alarm independent of the probability information, we should have observed differential responses to the insect and identified disease scenarios with the same probabilities. Although the expected value of death due to exposure to HIV is about equivalent to the expected value of death from hepatitis B, the fear of HIV appears to exceed the fear of hepatitis B. Perhaps the most important explanatory variable is the probability of certain death. The chances of being infected with HIV are small, yet the consequences are very serious. Fear of living for any length of time infected with a virus for which the outcomes are always fatal apparently overrides the concern that the initial chances of being infected are small. Conversely, accidental exposure to hepatitis B, although highly infectious, offers the hope that even if infected the victim has only about a 5% chance of ultimately dying of the illness. Thus, what at first appears to be irrational behavior in the face of alternative risks might actually be rational. Who would not prefer to live, no matter how long or short a time, in a state of hopeful uncertainty when it comes to death (as most of us do every day) than to be forced to alter our perception and live in a state of dismal certainty?

The results might also explain fears associated with other low-probability events that are perceived to have certain mortal outcomes. For example, the fear of being involved in an airplane crash appears to greatly exceed the fear of becoming involved in an auto crash, even though the probability of injury and death from auto crashes exceeds that from airplane crashes, given that many more auto crashes occur. We hope these results also offer insights into public attitudes that might lead to practical approaches to education. For one thing, it seems apparent that the customary use of statistics in allaying anxieties and enforcing precautions must be improved by incorporating the "rationally irrational" fears experienced by most, if not all, human beings.

This study has a number of limitations. The scenarios were hypothetical, and participation was restricted to college students. It might be argued that fears of accidental exposure to HIV and hepatitis B are related to factors other than those that we studied. For example, there is the issue of medical secrecy. Although information about hepatitis B is typically listed in the patient record, information about the HIV status of patients is typically absent. Thus, providers can take precautions against hepatitis B but do not have the information to alert them to take precautions against HIV. We cannot discount this explanation; however, we point out that in this study the greater fears of HIV exposure over hepatitis B exposure were demonstrated by subjects who were not health care providers and were not familiar with patient records. Furthermore, the island scenario produced results almost identical to those of the HIV–hepatitis B scenario and did not mention the names of the diseases.

Another limitation of the study is that these scenarios are not entirely realistic. For example, the AIDS vs hepatitis B scenario asked which vaccine the respondent would prefer. Unfortunately, there is no real AIDS vaccine, making the generalization to the real-life situation difficult. However, we suggest that the apparently excessive fear of HIV exposure is not an irrational manifestation, but rather the rational reaction to the prospect of living with the certainty of proximate death. □

What Is the Dentist's Occupational Risk of Becoming Infected with Hepatitis B or the Human Immunodeficiency Virus?

Eli I. Capilouto, DMD, ScD, Milton C. Weinstein, PhD, David Hemenway, PhD, and Deborah Cotton, MD, MPH

ABSTRACT

Surveys have shown that dentists are reluctant to treat persons infected with the human immunodeficiency virus (HIV). However, dentists are much more willing to treat patients with infectious hepatitis B virus (HBV). This study shows that the annual cumulative risk of infection from routine treatment of patients whose seropositivity is undisclosed is 57 times greater from HBV than from HIV, and that the risk of dying from HBV infection is 1.7 times greater than the risk of HIV infection, for which mortality is almost certain. (*Am J Public Health.* 1992;82:587–589)

Introduction

Practicing dentists are reluctant—and in many cases unwilling—to treat patients infected with the human immunodeficiency virus (HIV).[1,2] The frightening possibility of occupationally acquiring HIV may be the most significant factor in dentists' reluctance to treat potentially infected patients.[3,4] On the other hand, dentists are less concerned about becoming infected with infectious hepatitis, and are less frightened to treat patients with this disease.[2] Despite these differences in perceptions of risk and in concern over treatment of HIV patients versus infectious hepatitis patients, the risks associated with treatment of these patients have not been examined.

In this paper we quantify dentists' risk of occupationally acquiring HIV and hepatitis B virus (HBV) as a result of a percutaneous injury, the most likely and efficient means of occupational infection.[5–13] Specifically, we answer two questions: (1) What is the likelihood of infection from routine contact with asymptomatic patients, whose HIV or HBV status is likely to remain undisclosed in a routine medical history or dental exam? and (2) What is the risk of infection per known infected patient treated? The analysis addresses the risk of a general dentist who has neither received the hepatitis B vaccine nor acquired immunity from previous infection.

The answers to these questions take on greater importance following a report of a significant need for dental care among symptomatic HIV-infected patients[14] and disclosure of a single case in which five patients of an HIV-infected dentist were infected, presumably during the course of their dental treatment.[15]

Methods

Estimates of the dentist's risk of infection are made using the following deterministic model[16,17]:

$$\text{Cumulative Risk} = 1 - [p(1 - ib)^n + (1 - p)]^m,$$

in which the parameters that affect risk are represented as follows:

- p = the probability that any individual patient will be infected,
- i = the probability that the dentist will sustain a percutaneous injury while delivering therapy to an individual patient,
- b = the probability of viral transmission given a percutaneous injury,
- n = the number of visits by each patient, and
- m = the number of different patients treated.

In addition to the assumption of a random draw of patients, the model assumes the independence of all of the model's events. (See reference 17 for a complete discussion of the model.)

Parameter Estimates

Values for the parameter estimates in the model are derived from a variety of secondary data sources. The parameters and their corresponding estimates and references[1,18–34] are listed in Table 1. Mid-range estimates are used in baseline model fitting.

For the first research question (i.e., What is the infection risk from asymptom-

TABLE 1—Parameter Estimates and Cumulative Annual Risk of Infection for Human Immunodeficiency Virus (HIV) and Hepatitis B Virus (HBV)

Parameter (symbol in model)	Estimate Used in Model	Range of Estimates	Reference(s)
Probability of Patient Infection (p)			
HIV (%)	0.28[a]	(0.16, 1.3)[a]	18–23
HBV (%)	0.4	(0.75)[b]	24, 25
Probability of Infection Given Injury (b)			
HIV (%)	0.3	(0.13, 0.70)[c]	26
HBV (%)	12.0[d]	(12.0, 22.0)[d]	27–32
Probability of Percutaneous Injury per Visit (i)	0.26[e]	(0.09, 0.43)[e]	1, 33, 34
Annual Number of Patients (m)[f]	1380		34
Annual Number of Visits per Patient (n)[f]	2		34
Cumulative Annual Risk			
HIV (%)	0.006		
HBV (%)	0.34		

[a]Model estimates of the number of HIV-infected persons in the United States vary from 400 000 to 1 million.[18] These two extreme estimates and a mid-range estimate (700 000 persons) were applied to the 1990 US Census population figure of 249 million persons to produce seroprevalence estimates of 0.16%, 0.28%, and 0.4%. Direct seroprevalence studies of newborns in New York City yielded the upper prevalence estimate of 1.3%.[22]

[b]Only two representative studies of HBV prevalence were found.

[c]These estimates represent the 95% confidence bounds of an analysis[24] that pooled results from numerous studies.

[d]These estimates are derived from two studies that tested the efficacy of hepatitis B immune globulin and immune serum globulin (ISG) in health careworkers exposed to hepatitis B virus via needle stick. Subsequent to these trials, the availability of more sensitive radio immune assay tests and the reanalysis of the sera collected in the trials led the researchers to conclude that ISG was essentially a placebo. Hence, infection likelihoods are derived from the groups that received ISG. (See references 31 and 32 for a complete explanation).

[e]The annual number of percutaneous injuries reported by dentists in three different retrospective studies were applied to the mean number of annual visits for dentists in general practice.

[f]Although ranges are available for these estimates, they are not important to the central purpose of this research, which is to examine the comparative likelihoods of infection from HIV and HBV.

TABLE 2—Cumulative Risk (in percent) for Human Immunodeficiency Virus (HIV) and Hepatitis B Virus (HBV) Infection According to Number of Known Infected Patients Treated

No. Infected Patients Treated	Cumulative Risk (%)	
	HIV	HBV
1	0.0007	0.03
10	0.008	0.3
100	0.08	3.1
1000	0.78	26.8
2000	1.54	46.4
5000	3.82	78.9

Note. The parameter probability estimates (in percent) used in model fitting were as follows: for HIV, i = 0.26, b = 0.3, p = 1, n = 1; for HBV, i = 0.26, b = 12.0, p = 1, n = 1.

atic patients whose serostatus is unknown?), parameter estimates on patient visits are based on annual figures so that an annual cumulative risk of infection is obtained. For the second research question (i.e., What is the infection risk per known infected patient treated?), the probability of patient infection (p) equals 1 in the model. The cumulative likelihood of infection is estimated for patient visits ranging in number from 1 to 5000.

Results of Model Fitting

In the case in which the susceptible dentist presumably is unaware of his patients' serostatus, the cumulative annual risk of infection is 57 times as great for HBV as for HIV (0.34% versus 0.006%; Table 1), a difference attributable to the higher prevalence of HBV in the patient population and the more efficient transmission rate.

Conducting a one-way sensitivity analysis of the model fitting for HBV risk sheds light on the model's validity. Substituting the higher 0.22 transmission rate raises the estimated annual risk of HBV infection from 0.34% to 0.63%. Interestingly, this risk rate is similar to reported annual incidence rates of 5.6 and 6.2 per 1000 person-years obtained in epidemiologic studies[35,36] of dentists before the availability of hepatitis vaccine.

Table 2 presents the cumulative risks of infection according to number of patient visits by infected patients. After 5000 visits, the likelihood of infection is 79% for HBV and 3.82% for HIV, as a result of HBV's higher transmission rates. The numbers in Table 2 also demonstrate the relative risks for dentists under a policy that would shunt patients infected with HIV to certain dentists. For example, a dentist who treats 2000 HIV-infected patients in a year would have a risk of infection 190 times greater than that of a dentist who treats only 10 such patients (1.54 percent versus 0.008 percent).

Discussion

The results of this analysis raise an interesting issue concerning dentists' perception of the relative occupational risks from these two infections. If a dentist exposed to HIV seroconverts, the likelihood of the dentist's developing acquired immunodeficiency syndrome (AIDS) is believed to increase with duration of infection. In fact, development of AIDS within 12 to 15 years appears almost certain, according to current model estimations.[37,38] However, this analysis suggests that in this occupational setting the mortality risk from HBV may be higher than the risk from HIV, and in many of the cases death will be more immediate. According to the Centers for Disease Control, 1.4% of all reported hepatitis B cases in 1985 ended in death within the year.[39] Among those 40 and older, the death rate was 3.1%. If, as expected, another 10% became chronic carriers, then their risk of death from hepatocellular carcinoma over the next 30 years would be approximately 15%.[40] Factoring the likelihood of acute and long-term mortality into the risk of primary infection yields a mortality risk of 0.01% from primary HBV infection, a risk 1.7 times greater than the risk of becoming infected with HIV (0.006%).

Apparently, many dentists do not recognize these relative risks. In a survey of dentists,[2] only 31% responded that they would be willing to treat HIV-infected patients, whereas 73% said they would treat hepatitis patients. The protection afforded by hepatitis immunization (40% of the respondents had been immunized) may partially explain the greater willingness to treat hepatitis patients. If so, given our findings of high mortality risk from HBV exposure, serious policy alternatives to increase the number of dentists immunized against hepatitis should be implemented. Another likely explanation underlying the greater willingness to treat hepatitis patients may

be the differences in preferences for the health states associated with HIV and HBV infection.[41] In other words, however dreadful, the stigma and morbidity of the health states of HBV disease are preferable to similar dimensions of HIV disease.

Finally, this analysis raises implications for the policy favored by most practicing dentists of referring HIV-infected patients to public health clinics, dental schools, and hospitals for treatment. According to the results shown in Table 2, such a policy would result in a maldistribution of the risk. Are dentists at high risk cognizant of their level of risk? Should dentists at high occupational risk be paid a wage premium for their incurred risk? If so, how much? The model used in this analysis can be helpful in providing answers to such questions. In addition, the model can be expanded to assess the reductions in risk that can be obtained from infection control proposals, and to weigh such benefits against their respective costs. □

Prevalence of HIV Antibodies in Transsexual and Female Prostitutes

Baruch Modan, MD, DrPH, Reuven Goldschmidt, MD, Ethan Rubinstein, MD, Ami Vonsover, PhD, Marion Zinn, Rachel Golan, BSc, Angela Chetrit, BSc, and Tamar Gottlieb-Stematzky, PhD

ABSTRACT

Human immunodeficiency virus (HIV) prevalence was studied in an unselected group of 216 female and transsexual prostitutes. Subjects were asked about age, biological sex, marital status, children, length of occupation, sexual practices, and drug abuse history. Blood was drawn on site.

All 128 females who did not admit to drug abuse were seronegative; 2 of the 52 females (3.8%) who admitted to intravenous drug abuse were seropositive. In contrast, 11.1% of the 36 male transsexuals (including 3 out of 32 non–drug abusers) were seropositive.

The results support the notion that vaginal transmission of HIV is less effective than anal transmission. (*Am J Public Health.* 1992;82:590–592)

Introduction

We report the initial results of a survey aimed at defining the prevalence of human immunodeficiency virus (HIV) seropositivity in a population of transsexual and female prostitutes working side by side. To the best of our knowledge no data on HIV infection among transsexuals is available.

Method

During a 36-month period, a multidisciplinary team manned a van that visited the major location of open prostitution in the Tel Aviv area, located on a northern beach of the city. To cover as wide a proportion of the prostitute population as possible, we visited the locale at different hours of the day approximately once every 6 weeks during the first year and approximately every 6 months subsequently. Although prostitution is not legal in Israel, the laws against it are not usually enforced. According to unofficial police estimates, the study covered at least 70% of Tel Aviv prostitutes known to the police.

During each visit a short demographic questionnaire was filled out by an interviewer. Informed consent was also obtained. The questions asked included questions about age, sex, marital status, number of children, years on the job, intravenous drug abuse (IVDA), and sexual practices.

As reported by the study subjects during the interviews, the Tel Aviv transsexual prostitute community is considered to comprise between 35 and 40 persons who practice prostitution in the same locale. These are biologically born males who live and dress as women. Most of them have either undergone castration or are in the process of getting ready to have such an operation. They are indistinguishable physically from the female prostitutes and share the same client population. They all reported being on continuous estrogen maintenance. About 25% of those interviewed reported a sex-change operation that included the forming of an artificial vagina.

A sample of blood was drawn on site, and specimens were transferred to the Chaim Sheba Medical Center laboratories. All serum samples were tested blindly for antibodies to HIV by a commercial enzyme-linked immunosorbent assay (ELISA kit, ELAVIA, Institute Pasteur, France). All sera found to be positive by ELISA were confirmed by an immunoblot assay (Western blot technique) using a commercial kit (Dupont Biotech Research Laboratory, Ind., USA), interpreted according to the supplier's instructions.

Results

The 216 individuals examined included 180 biological women and 36 transsexuals who had been born males. Twenty-six percent of the females and 10.3% of the males reported previous or current IVDA. All of the biological males admitted to anal intercourse at some time during their sexual lives. In contrast, less than 10% of the female prostitutes admitted to having engaged in anal intercourse.

For the total group, ages ranged between 18 and 57, with a mean of approximately 30 years. There was no difference in mean age between females who admitted to drug abuse, the rest of the female group, and the transsexuals.

This paper was submitted to the Journal May 13, 1991, and accepted with revisions November 12, 1991.

Fifty percent of the females and 42.9% of the males had practiced prostitution for 5 years or longer; 22.9% and 28.6%, respectively, had practiced it for more than 10 years. There was no difference in length of occupation between females who reported IVDA and those who did not. Condoms were used by both sexes during the study period. More detailed information on the frequency of this practice could not be obtained.

Table 1 presents the numbers and percentages of seropositive subjects by biological sex and reported history of drug abuse. Close to 11% of the transsexuals were found to be HIV positive, as compared with only 1.1% of the total group of females. Breakdown by drug abuse history shows that 3.8% of the females who admitted to IVDA were HIV positive. *All* females who denied a history of IVDA were seronegative. Among the transsexuals, there were 3 seropositive among the 32 who did not admit to IVDA. The differences between the transsexuals and the females are significant at the $P < .01$ level by Fisher's Exact Test.

To estimate the effect of IVDA and gender, data were stratified by these variables. The odds ratio for female gender was 20.8 (90% confidence interval, 4.4–101.7); the odds ratio for IVDA was 7.3 (90% confidence interval, 1.6–34.3).

TABLE 1—Age Distribution of the Study Population and Percentage Seropositive, by Sex and Drug Abuse

Category	Age				Seropositive	
	n	Mean	SD	Range	n	%
Females, no drugs	128	31.1	7.5	19–54	—	0.0
Females, drug history	52	28.1	5.9	19–40	2	3.8
Total females	180	30.2	7.2	19–54	2	1.1
Males	36	31.0	9.6	18–57	4	11.1

Note. Age was unclear in 1 female and 3 males.

Discussion

HIV has been isolated from genital secretions as well as from genital ulcers, saliva, semen, and seminal plasma of AIDS patients.[1–8] Yet, although the male to female route has never been disputed,[9–12] the exact mechanism of transfer has not been fully established.

The discrepancy between male and female prostitutes working side by side suggests that female prostitutes who are not drug abusers may be at less risk for HIV transmission than are transsexuals. There are a number of possible reasons for this discrepancy: a lower frequency of condom use, a possible increase in efficiency of transmission of HIV by an artificial vagina in the transsexual population (e.g., more friable mucosa), and a possible role of estrogen replacement. Still, most of the subjects in both the male and female groups reported full use of condoms at the time of the study.

The fact that all of the seropositive women admitted to drug abuse is in line with other studies of prostitutes in Western societies. A thorough search of recent literature fails to demonstrate unequivocal seropositivity among British,[13] French,[14] German,[15] Italian,[16] or Dutch[17] prostitutes without drug histories. In Greece,[18] 6% of 200 prostitutes examined were reported to be seropositive; however, their lack of drug histories may be questioned. In the same context, 5% seropositivity was observed among female prostitutes seen in selected venereal disease clinics in the United States.[19–21] Yet anal intercourse, genital ulcers,[21] or direct vaginal seminal contact[22] were not ruled out.

The data are also compatible with the rarity of female-to-male transfer of HIV,[22–28] and they may raise the question of whether female infection occurs primarily outside the vaginal route. Even if some of the prostitutes had falsely denied drug abuse, the resulting misclassification would have led to a bias in the opposite direction. Unfortunately, no male partners of these female prostitutes could be included in the study. To address the question of their infection status, one would have to prospectively follow a group of male partners sexually exposed to HIV-infected prostitutes. This mission would have been impossible to accomplish in a population that volunteered to participate in a study that promised anonymity. Because the transsexuals had more anal contacts in their pasts than did the female prostitutes, our findings may suggest that vaginal transmission of HIV is less effective than anal transmission. On the other hand, the role of more effective barrier precautions taken by some of the female prostitutes cannot be ruled out. □

Predictors of Condom Accessibility among Hispanics in San Francisco

Barbara V. Marin, PhD, and Gerardo Marin, PhD

ABSTRACT

Ready access to condoms can be an important means of slowing the spread of sexually transmitted diseases and human immunodeficiency virus. We identified the factors associated with keeping or carrying condoms in a random-digit dialing survey of 522 Hispanic adults aged 18 to 65 years in San Francisco. Overall, more Hispanic men reported having condoms than Hispanic women (55.2% vs 23.8%). Hispanic men also reported much higher levels of risky sexual behavior than Hispanic women. Condom promotion efforts with Hispanics will require different approaches for each gender. (*Am J Public Health.* 1992;82:592–595)

Introduction

Sexually transmitted diseases (STDs) and acquired immunodeficiency syndrome (AIDS) are major health problems for Hispanics in the United States. While Hispanics make up approximately 8.5% of the population of the United States, they account for over 15% of AIDS cases,[1] and the incidence of AIDS attributable to heterosexual contact is 4 times higher for Hispanic men and 11 times higher for Hispanic women than for non-Hispanic Whites.[2] Currently, the rates of gonorrhea, syphilis, and chancroid are all many times higher for Hispanics than for non-Hispanic Whites in the United States.[3–5]

Appropriate condom use is an important method of preventing the spread of human immunodeficiency virus (HIV) and other STDs among Hispanics. Rates of condom use among married women, including Hispanics, remain low,[6] and rates of use for unmarried Hispanics are rarely reported. To explore and describe the demographic, attitudinal, and behavioral factors associated with condom use among Hispanics and to identify areas that should be emphasized in health education campaigns to promote condom use in this group, we surveyed a random sample of Hispanic adults in San Francisco by telephone.

Methods

Procedure

We used a modified Mitofsky-Waksberg method of random-digit dialing[7] to survey Hispanic adults in San Francisco 18 to 65 years of age. The refusal rate was 8.4%.

Measures

To assess condom accessibility, respondents were asked: "Do you keep condoms somewhere or carry them with you?" Also, they reported their frequency of condom use in the previous 12 months (always, often, sometimes, seldom, or never) and frequency of use with their primary sexual partner, with all male partners, and (in the case of men) with all female partners. Predictor variables included embarrassment (a lot or a little vs none) in buying, using, or, in the case of

women, asking a partner to use condoms; proportion of correct responses to 11 items about AIDS and HIV from the National Center for Health Statistics AIDS supplement to the National Health Interview Survey; and male respondents' beliefs about how commonly condoms are used by men in San Francisco. High-risk sexual behaviors in the 12 months prior to the survey were also predictors, defined as follows: "High-risk" men reported sexual relations with more than one female partner, with a prostitute, or with another man. "High-risk" women reported sexual relations with more than one male partner. Demographic predictors included employment status, income (yearly income of less than $15 601 vs $15 601 or more), age (less than 35 vs 35 or more), religiosity, and marital status (married or living together vs other). A five-item acculturation scale measured use of English and/or Spanish,[8] and the mean of responses was used to define low (1 through 2.99) and high (3.0 through 5.0) acculturation.

Analysis

Logistic regressions were conducted separately for each gender using the condom accessibility item as outcome and the other measures as predictors. To avoid problems with multicollinearity, education was not entered, as it correlated highly (.48) with acculturation.

Results

Five hundred twenty-two Hispanic adults in San Francisco were interviewed by telephone in autumn 1989. Table 1 includes relevant demographic statistics for the sample as a whole as well as for each gender. Table 2 presents specific sexual behaviors reported by the sample, and Table 3 indicates condom use among respondents reporting low- and high-risk sexual behaviors. Tables 4 and 5 present the results of the multiple logistic regressions separately for men and women. Table 6 includes information on where respondents obtain and keep condoms.

ated with prostitution and extramarital relationships in Latin America.[9] However, only a third of men at risk reported "always" using condoms with all partners. Culturally appropriate campaigns to promote condoms to Hispanic men may be most successful if targeted to those with multiple partners.

Hispanic women, especially the less acculturated, often did not keep or carry condoms. A small group of women (5%) reported placing themselves at risk through multiple partners, and these women were somewhat, though not significantly, more likely to carry condoms. An unknown, but probably larger, number of Hispanic women may be placed at risk when their partners engage in risky behaviors. These women are likely to resist condom promotion efforts, since they reported that they were often embarrassed to buy or ask their partner to use condoms and that they were more likely to obtain condoms from health centers or friends than to purchase them.

Traditional Hispanic culture emphasizes the need for men to express their sexuality and for women to avoid such expression.[10,11] Both men and women often reported being embarrassed to buy condoms, especially those who reported not having condoms. Embarrassment has

Discussion

In this study, more Hispanic men reported having condoms available than Hispanic women. Hispanic men also reported much higher levels of risky sexual behavior than Hispanic women. Those men who had multiple sexual partners were more likely to have condoms available. This is not entirely surprising, since condom use has traditionally been associ-

often been associated with inconsistent condom use in other populations,[12,13] suggesting that interventions to increase comfort with sexual topics could be useful adjuncts to condom promotion campaigns among Hispanics. Given the low proportion of less-acculturated (i.e., Spanish-speaking) women who had condoms, these women may be in special need of such an intervention.

This study has important limitations. Hispanics in San Francisco are different demographically from those in the Northeast, who tend to be predominantly from Puerto Rico and other Caribbean countries. The HIV/AIDS epidemic has affected a disproportionate number of Puerto Ricans in the northeastern United States,[14,15] although levels of STDs are high among Hispanics in most areas of the United States. An additional limitation of most studies of condom use is that self-reports of sexual behaviors can produce embarrassment and a desire to misrepresent actual behavior.

The high rates of sexual activity outside the primary relationship for Hispanic men in this study suggest that AIDS/STD prevention interventions targeting Hispanic men might include a component designed to improve sexual satisfaction within the primary relationship. In one study, Hispanic women, especially those who were married, reported low frequency of sexual intercourse and low sexual satisfaction.[16] For women with partners who engage in high-risk activities, interventions are needed to increase the awareness of their own risk and to improve their sexual communication skills; also, there is a need for the development, testing, and promotion of methods of protection that are not dependent on men's behavior.[17] □

Legal Needle Buying in St. Louis

Wilson M. Compton III, Linda B. Cottler, Scott H. Decker, Douglas Mager, and Roosevelt Stringfellow

ABSTRACT

This study sought to determine if and why barriers to the over-the-counter purchase of syringes in the St. Louis metropolitan area might exist, given that no ordinance prohibits such a sale there. Two male research assistants (one African American, one White) approached 33 of the area's pharmacies to buy syringes. In 14 of those pharmacies, either the purchase was refused or the minimum number of syringes that could be bought was so large (at least 100) that the sale was not practical. Racial bias in rates of refusal and implications for prohibiting or restricting legal availability of syringes are discussed. (*Am J Public Health.* 1992;82:595–596)

Introduction

International studies have shown that the legal purchase of sterile syringes may be an important factor in reducing the spread of human immunodeficiency virus (HIV). On the other hand, obstacles to the purchase of sterile syringes may contribute to the rapid spread of HIV infection.[1,2] In France, the liberalization of regulations for purchasing syringes resulted in lower rates of needle sharing and increased use of sterile syringes by intravenous drug users (IVDUs).[3] In Edinburgh, Scotland, however, the rapid spread of HIV among IVDUs coincided with a police crackdown on the supply of legally available syringes.[4]

The State of Missouri, like 38 other states, has no ordinance prohibiting the over-the-counter sale of sterile syringes. Such legal and apparently easy availability of sterile syringes may be one of the reasons HIV infection rates are low (approximately 3%) among St. Louis' IVDU population[5] compared with rates in New York or New Jersey (50% to 60%).[6–8]

To describe the availability of legal needles, we designed a project to mimic the purchase of syringes by IVDUs at pharmacies throughout the St. Louis area, particularly in neighborhoods where intravenous drug use is prevalent. This project began at a time when we heard that local pharmacists had their own "War on Drugs" campaign, which included refusing to sell syringes to customers without proof of medical need.

Methods

A comprehensive list of pharmacies (n = 360) was drawn from the listings in the local Yellow Pages. To provide a widespread distribution, sample pharmacies were selected that were maximally distant from one another within defined geographic areas. A map of the St. Louis area was divided into 10 comparably sized areas, using major thoroughfares as dividing lines. One southwest suburban sector was excluded from sampling because police data indicated little drug-related activity. Four pharmacies were then selected within each sector, for a total of 36 pharmacies scheduled for sampling within nine geographical sectors.

During field work, several pharmacies were found to be out of business, so the nearest available pharmacy was substituted. Of the 36 selected pharmacies, 33 were visited during one week in May 1990 for a 92% completion rate. Of those visited, 25 were part of major chains; 8 were independent or affiliated with minor chains, hospitals, or medical centers.

The two male research assistants who carried out the buying project were 41 and 46 years old. One was African American and one was White. Their attire dur-

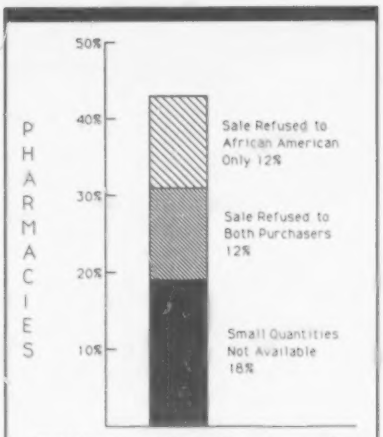

FIGURE 1—Obstacles to needle purchase.

ing the project was casual. They did not discuss the needle-buying project with pharmacy personnel and did not claim to be drug users. In addition, each was blinded as to the other's outcome.

Each research assistant approached the same pharmacy on consecutive days at approximately the same time of day and attempted to purchase syringes by saying "I need a pack of 28-gauge, 100-unit insulin syringes, please." A pack referred to a 10 pack. This size and type of syringe was chosen because a San Francisco study and our ethnographic consultant confirmed that it is the size used most often by IVDUs.[9]

The data collected included location and name of store; time of day and date when purchase was attempted; race, sex, and estimated age of pharmacy staff person confronted; and cost of syringes (if purchased). If the purchase was refused, the researchers engaged the pharmacist/clerk in casual conversation to determine the reasons for refusal.

Results

As shown in Figure 1, eight pharmacies (24%) refused to sell syringes; six others (18%) would not allow small quantities of syringes to be purchased. This meant that the purchase of a 10 pack or less was possible at 19 pharmacies (58%). Eight pharmacies refused to sell without confirmation of a medical condition; of those, four refused to sell syringes to both research assistants and four refused the African American only.

The predominant reason given for refusal to sell was simply "store policy." At certain stores, however, other reasons were given, which confirmed our original suspicions that pharmacists were waging their own War on Drugs. Two pharmacists reported that selling syringes is "too much trouble." Another reported that only a few specific customers could buy syringes and only by prior arrangement. A fourth reported that he would not sell syringes without a prescription because of the high incidence of drug abuse in the neighborhood. A fifth stated that he would not sell to "drug users."

The cost of syringes varied from $1.92 to $4.28 for a 10 pack. In six pharmacies, a minimum of 100 syringes could be purchased, at a cost of about $25; however, such a sale would be impractical for most drug addicts. In two pharmacies, single syringes could be purchased.

Conclusions

This needle-buying project provides baseline data concerning the availability of hypodermic syringes to the IVDU in a large midwestern city where no laws restrict the sale of such items. Almost half the pharmacies (42%) either refused to sell syringes or sold them only in costly quantities.

Evidence of possible racial bias in the sale of syringes to the white researcher but not to the African-American researcher was found and may be particularly important for African-American IVDUs. It is ironic that one of the populations most in need of prevention measures to combat the spread of acquired immunodeficiency syndrome (AIDS) is denied access to sterile syringes even when access is not legally denied.[10] African-American IVDUs may therefore be placed at higher risk for contracting AIDS because of racial bias in availability of sterile syringes. Users, especially if African American, may have little option but to sharpen, share, and reuse syringes. □

Acknowledgments

This study was funded in part by grant DA-06163 from the National Institute on Drug Abuse. However, the purchase of syringes was funded through private, nongovernmental funds.

Risk Factors Associated with Antibodies to Leptospires in Inner-city Residents of Baltimore: A Protective Role for Cats

James E. Childs, ScD, Brian S. Schwartz, MD, MS, Tom G. Ksiazek, PhD, DVM, R. Ross Graham, PhD, DVM, James W. LeDuc, PhD, and Gregory E. Glass, PhD

ABSTRACT

Leptospiral antibody prevalence was 16% in residents of Baltimore. Seropositivity was associated with age, gender, race, and bird ownership, and negatively associated with contact with rat excrement and cat ownership. Current cat ownership reduced the antibody risk associated with age and race from odds ratios (95% confidence interval) of 3.3 (2.0, 5.5) and 3.3 (1.1, 9.3), respectively, to the baseline level. These data establish the high prevalence of leptospiral antibody in Baltimore and suggest a protective role for cats in reducing the risk of human infection. (*Am J Public Health.* 1992;82:597–599)

Introduction

Leptospirosis is an acute, febrile spirochetal disease most commonly affecting the liver and kidneys. Although leptospirosis can be debilitating, infection frequently runs a milder or even asymptomatic course that may go undiagnosed.[1]

Leptospires (*Leptospira interrogans*) infecting humans are primarily maintained by warm-blooded vertebrates.[2] In cities, the Norway rat (*Rattus norvegicus*)[3–7] and dog[8] have been regarded as major reservoirs. The degree of human–animal contact with wild and domestic animals may be an important determinant of infection. In this paper we describe the prevalence of antibodies to leptospires in an inner-city population and examine risk factors associated with seropositivity.

Methods

Study Population

Sera and questionnaires were obtained from persons visiting a sexually transmitted disease clinic between March 1987 and December 1988, as described previously.[9,10] Subjects were primarily male (71.4%), Black (94.3%), and young (median age = 23.5 years); 99% lived within the city limits.[10]

Data Collection

Respondents signed informed consent forms and were individually interviewed. Verbal responses were recorded to questions of age; history of residence; yearly income; occupation; travel; frequency of rat and mouse sightings within current and past residences, on current or past streets and alleys, and at current or past work place; history of contact with rodents through trapping, excrement, handling animals, or receiving rodent bites; and current or past ownership or living with cats, dogs, or other pets (classified as mammal, bird, or amphibian/reptile/fish). Observed race and sex were noted. Blood from respondents was centrifuged and serum stored at −20°C.

Serology

Sera were screened for immunoglobulin G (IgG) by enzyme-linked immunosorbent assay (ELISA) using the serovar mwogolo, prepared by standard methods,[11] as antigen. Tests using this antigen are genus specific (R. R. Graham, unpublished data 1986). Sera reactive at 1:200 dilution were considered positive. A subsample of 37 sera positive by IgG ELISA were also tested by the microscopic agglutination test (MAT)[12] and screened for immunoglobulin M (IgM) by ELISA. Serogroups (serovars) used in MAT included Australis (*australis*), Autumnalis (*autumnalis*), Ballum (*ballum*), Bataviae (*bataviae*), Canicola (*canicola*), Grippotyphosa (*grippotyphosa*), Sejroe (*hardjo*), Icterohaemorrhagiae (*icterohaemorrhagiae, copenhageni*), Pomona (*pomona*), Pyrogenes (*pyrogenes*), Shermani (*shermani*), and Tarassovi (*tarassovi*). A MAT titer of 1:50 was considered positive for all serovars except *shermani*, where 1:800 was used because of the potential autoagglutination of the antigen.

TABLE 1—Crude and Adjusted Odds Ratios for Variables Associated with Leptospiral Antibody in Baltimore, Md, 1987–1988

	Crude Odds Ratio (95% Confidence Interval)		Adjusted[a] Odds Ratio (95% Confidence Interval)	
Age (>19 vs ≤19)	2.3	(1.5, 3.5)	2.8	(1.8, 4.5)
Sex (male vs female)	1.5	(1.0, 1.9)	1.5	(1.0, 2.2)
Race (Black vs other)	1.8	(0.8, 3.9)	2.0	(0.9, 4.5)
Income (≤$8000 vs >$8000)	1.2	(0.8, 1.7)	1.6	(1.1, 2.4)
Contact with rat excrement (some vs none)	0.7	(0.5, 1.1)	0.5	(0.3, 0.9)
Current cat ownership (none vs ≥1)	2.1	(1.1, 3.8)	1.9	(1.1, 3.5)
Bird ownership (ever vs never)	1.4	(0.8, 2.5)	1.7	(1.0, 3.1)

[a]Adjusted for all other variables in table.

TABLE 2—Adjusted[a] Odds Ratios Associated with Age, Race, and Sex after Stratification by Current Cat Ownership

	Current Cat Ownership			
	None		One or More	
	Odds Ratio	95% Confidence Interval	Odds Ratio	95% Confidence Interval
Age (>19 vs ≤19)	3.3	2.0, 5.5	0.8	0.3, 2.8
Race (Black vs other)	3.3	1.1, 9.3	0.4	0.1, 1.6
Sex (male vs female)	1.5	1.0, 2.3	1.4	0.4, 1.6

[a]Adjusted for age, sex, race, income, contact with rat excrement, current cat ownership, and bird ownership.

All ELISA positive and 163 negative sera were tested for cross reactivity to *Treponema pallidum* by a standard rapid plasma reagin (RPR) assay.[13]

Data Analysis

Analyses were performed with SAS®[14] or BMDP®[15] software systems. Variables were dichotomized to ease interpretation of results and to allow calculation of odds ratios. Crude odds ratios were calculated for the association between all study variables and leptospiral serological status. Stratification and logistic regression were used to assess interactions between variables and to control for potential confounding variables.[16] Variables thought to be important a priori were included in initial logistic regression models, and the contribution of other variables was assessed by partial F tests. After selection of a model, all possible interactions between variables were assessed and retained if statistically significant ($P < .05$) or if felt to be biologically important.

Results

The prevalence of ELISA antibodies to leptospires was 16% (185/1150), with a single positive IgM titer found. Titers by MAT ≥1:50 to one or more serovars were found in 31 of 37 ELISA positive sera. The most common serotypes eliciting a response were Batavia (20/37) and Icterohaemorrhagiae (16/37). There was no indication of significant cross-reactivity with *T. pallidum* ($\chi^2 = 1.88$, $P = .17$).

Crude (unadjusted) analyses showed associations of leptospiral antibody with age and male gender, but not with other demographic variables. Current ownership of cats was significantly associated with lower antibody prevalence. None of the rodent exposure variables were associated with antibody.

Logistic regression indicated that age (≥19), sex (male), Black race, and low income (≤$8000) were independent risk factors associated with leptospiral antibody (Table 1). Self-reported contact with rat excrement was negatively associated with seropositivity.

History of bird ownership (chickens or pet birds) was positively associated, and cat ownership negatively associated, with antibody. An interesting interaction was observed between cat ownership and both age and race: Age and race were risk factors for seropositivity only in persons who did not own cats (Table 2).

Discussion

This study documented a high prevalence (16%) of leptospiral antibody in an inner-city population. Associations between antibody and age and sex were expected based on studies of leptospirosis in the United States.[17] However, the data also indicated a potential protective role for cat ownership in reducing the risk of infection.

Studies conducted in Detroit have also reported high levels of leptospiral antibody (≥30%) in inner-city children under 6 years old.[18] As in Baltimore, with three cases of leptospirosis documented since 1987 (R. Dunning, written communication 1991), disease was uncommon in Detroit. Leptospirosis is a self-limited condition with usual spontaneous recovery within 4 to 9 days.[19] Afflicted persons may not seek medical care, and the disease also is underreported.[19]

The serological tests we used indicated few recent infections. Specificity of our ELISA assay was indicated by the 84% concordance with MAT and lack of cross-reactivity with RPR tests. Other serosurveys have found that up to 35% of ELISA positive sera will not react by MAT.[20]

Risk of leptospirosis associated with animals has rarely been explored beyond incriminating a species during a case investigation or epidemic,[21,22] or stratification of human antibody prevalence based on animal contact.[23,24] We found a lowered risk of leptospiral antibody for persons reporting past history of exposure to rat excrement. This study variable may have measured rat awareness rather than "risky" behavior. The clearest and most interesting association was between decreased leptospiral seropositivity and cat ownership. Cats could reduce the risk of rodent-borne leptospirosis if they reduced human contact with the reservoir. The relationship between cat ownership and race is also interesting, as Blacks in Baltimore own fewer cats than do Whites.[25] This difference in cat ownership could place Black residents at increased risk for contact with rodents and the zoonoses

they carry, and could contribute to the increased prevalence of antibody in Black residents.

Cats have been linked to human infection with several pathogens (e.g., *Toxoplasma gondii*[26] and *Yersinia pestis*[27]), but, to our knowledge, never in a protective role. These novel observations deserve further research and confirmation by other studies. □

Characteristics Related to Elderly Persons' Not Eating for 1 or More Days: Implications for Meal Programs

Edward A. Frongillo, Jr, PhD, Barbara S. Rauschenbach, PhD, Daphne A. Roe, MD, and David F. Williamson, PhD

ABSTRACT

We examined how social, economic, location, health, and food need characteristics are related to elderly persons' not eating for 1 or more days. The following variables were positively related to not eating: ethnicity, location, receipt of Medicaid, living alone, health problems, mobility, age less than 80 years, cancer, nausea, difficulty swallowing, diarrhea, loss of appetite, and receipt of food from a food pantry. These results have implications for allocating meal program funds, screening clients, and monitoring whether clients eat regularly. (*Am J Public Health.* 1992;82:600–602)

Introduction

The demand for federally funded nutritional meals programs for the elderly has increased since 1972, when such programs were first authorized.[1] Persons 60 years or older and their spouses are eligible; priority is given to persons with incomes below the poverty line, to minority persons, and to the physically or mentally disabled or socially isolated. To reach those in greatest need, most agencies screen applicants for age, mobility, current illness and disability, and social isolation. However, few studies are available on characteristics of the elderly that are related to poor nutritional status, and these studies either did not explain variation in status or examined a limited set of explanatory variables.[2–15] In this paper we examine how economic, location, social, health, and food needs characteristics affect elderly persons' not eating for 1 or more days (Figure 1).

Methods

Meal program staff in New York City (NYC) and 31 New York State counties interviewed 4017 new home-delivered meal (HDM) clients in their homes from 1984 to 1986 before they began receiving meals. In 1985 and 1986, a self-administered survey assessed 2648 congregate meal (CM) clients already receiving meals.

The variable not eating for 1 or more days was modeled using logistic regression.[16] Dummy coding was used for most variables, the reference being those without the characteristic.[17] Receipt of Medicaid indicated economic status because poverty status had many missing values. Needing help with food shopping was omitted because it was closely related to needing help with food preparation. The reference for ethnicity, living in NYC, and their interaction was White living outside of NYC. The reference for sex, living alone, and their interaction was female not living alone. Number of health problems quantified diseases other than cancer. HDM and CM clients were analyzed separately because the two groups differed in health status, mobility, and whether they were receiving meals. Model fit was measured by area under the receiver operating characteristic (ROC) curve.[18]

Additional variables were available for 1985 and 1986 HDM clients: education, receipt of Supplemental Security Income, receipt of food from a food pantry, use of commodity foods, loss of appetite, and having diarrhea, nausea, difficulty swallowing, depression, constipation, incontinence, indigestion, dental problems, or impaired vision. The best extended model, of several fitted using these additional variables, was compared with the original model after it was refitted to the 1985 and 1986 subsample.

Results

The percentage of clients not eating for 1 or more days was 3.4% for CM and 17.5% for HDM clients. The variables that were important in explaining not eating were similar for the HDM and CM clients (Tables 1 and 2). The positively related variables were as follows: White living in NYC, minority living outside NYC, minority living in NYC, receiving Medicaid, male living alone, number of health problems, and being mobile only with aid. Needing help with food preparation was also found to be important, but its addition to the models made mobility no longer important and so it was excluded. Age 80

This paper was submitted to the Journal August 2, 1990, and accepted with revisions July 18, 1991.

years or older was negatively related. Having cancer and being chair- or bed-bound were positively related only for HDM clients; only 2% of CM clients had cancer and none of them were chair- or bed-bound. The effect of living alone differed with sex and with client group; the effect of ethnicity differed with location and client group. The magnitudes of the regression coefficients for the seven variables common to both models were smaller in the model for HDM clients. The ROC curve area was 0.82 for CM clients and 0.66 for HDM clients.

The best extended model for the 1985 and 1986 HDM clients included five additional variables: nausea, difficulty swallowing, diarrhea, loss of appetite, and receiving food from a food pantry (Table 3). The ROC curve area for the extended model (0.73) was larger than that for the original model refitted to the 1985 and 1986 subsample (0.66), indicating a better fit for the extended model.

TABLE 1—Variables Explaining Not Eating for 1 or More Days among Home-Delivered Meal Clients (n = 3353)

	Percentage of Sample	Regression Coefficient	Odds Ratio	95% CI for Odds Ratio	
Constant		−2.04			
Minority living outside NYC	3	0.27	1.31	0.77	2.24
White living in NYC	16	0.37	1.45	1.13	1.86
Minority living in NYC	6	0.84	2.33	1.67	3.24
Receiving Medicaid	21	0.45	1.58	1.27	1.96
Age 80 years or older	41	−0.32	0.73	0.59	0.89
Female living alone	44	0.03	1.03	0.82	1.30
Male not living alone	17	−0.54	0.58	0.42	0.81
Male living alone	15	0.23	1.26	0.94	1.69
Number of health problems[a]	1.3	0.09	1.21	1.02	1.43
Having cancer	8	0.73	2.08	1.55	2.79
Being mobile with aids	46	0.16	1.17	0.96	1.43
Being chair- or bed-bound	6	0.74	2.10	1.46	3.01

Note. CI = confidence interval; NYC = New York City. The likelihood ratio chi-square statistic for comparison with the model having only the constant was 143.68 (12 *df*). The area under the ROC curve was 0.66. [a]The mean is shown (range, 0 to 4). The odds ratio and 95% CI were calculated for two times the regression coefficient; the factor of two corresponded to two standard deviations. This calculation allowed for a more meaningful comparison of the odds ratio with that of the other variables.

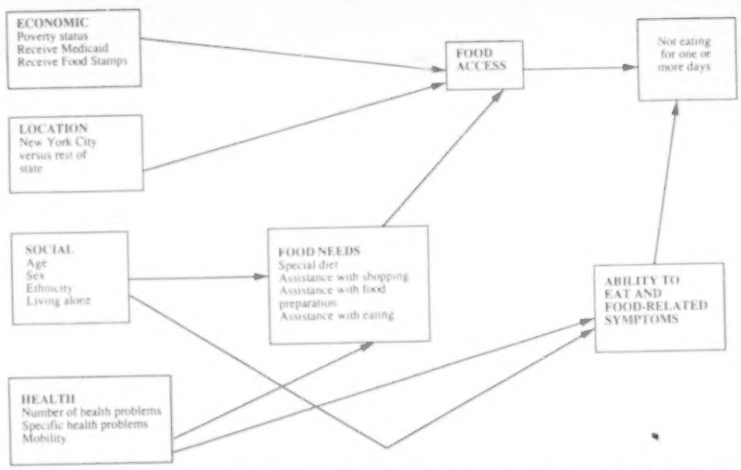

FIGURE 1—Conceptual map for the effect of economic, location, social, health, and food needs characteristics, through their effect on both access to food and the ability and desire to eat, on not eating for 1 or more days.

Discussion

HDM clients had more characteristics related to not eating than did CM clients, but this explains only some of the group difference in the percentage of those who did not eat; the larger constant in the model for the HDM clients indicates that their odds of not eating were greater, even when they had none of the characteristics included in the model. The model for HDM clients did not explain not eating as well as did the model for CM clients. Some characteristic(s) other than those included affected whether the HDM clients ate regularly. Indeed, the extended model for HDM clients was substantially better at explaining who did not eat for 1 or more days.

By increasing clients' access to food, participation in the CM program may have reduced the odds of their not eating, because these clients were already receiving meals. The home-delivered meal program could be expected to have a similar effect on clients once they began receiving meals.

For HDM clients, the finding that living alone was positively related to not eating among men, but not among women, is similar to that previously reported with national survey data.[13-15] However, just as this interaction did not occur for both groups of clients in our study, it occurred in only some of the previous studies and for only some measures of eating behavior.

The lower odds of not eating among persons 80 years or older may seem counterintuitive. Persons who live to age 80 may have certain characteristics, not included in the models, that allow them to eat more regularly.

The characteristics we found to be related to not eating can help determine allocation of meal program funds. Counties with more elderly residents having characteristics related to not eating for 1 or more days should be considered to be in greater need. These characteristics can also be useful for developing screening criteria to ensure that those most likely to not eat regularly are enrolled in the programs, and for nutritional monitoring of clients after enrollment. Elderly persons who have many of the characteristics at the time of enrollment may be monitored to ensure that they do not subsequently go without food.

Some CM clients did not eat for 1 or more days despite their participation in the CM program. Most programs provide meals 5 days per week, but these clients may need congregate meals all 7 days. Among HDM clients, those with nutrition-related health problems may need nutritional counseling, medical attention, and encouragement—in addition to meals—to ensure adequate nutrition. □

TABLE 2—Variables Explaining Not Eating for 1 or More Days among Congregate Meal Clients (n = 2240)

	Percentage of Sample	Regression Coefficient	Odds Ratio	95% CI for Odds Ratio	
Constant		−5.50			
Minority living outside NYC	6	1.11	3.05	1.47	6.32
White living in NYC	14	1.41	4.08	2.28	7.29
Minority living in NYC	14	0.85	2.34	1.25	4.40
Receiving Medicaid	20	1.16	3.20	1.98	5.18
Age 80 years or older	18	−0.99	0.37	0.17	0.80
Female living alone	42	0.94	2.56	1.17	5.59
Male not living alone	19	0.62	1.86	0.72	4.86
Male living alone	16	1.58	4.85	2.13	11.07
Number of health problems[a]	1.3	0.29	1.30	1.19	2.72
Being mobile with aids	18	0.49	1.63	0.98	2.72

Note. CI = confidence interval; NYC = New York City. The likelihood ratio chi-square statistic for comparison with the model having only the constant was 125.43 (10 *df*). The area under the ROC curve was 0.82. [a]The mean is shown (range, 0 to 4). The odds ratio and 95% CI were calculated for two times the regression coefficient; the factor of two corresponded to two standard deviations. This calculation allowed for a more meaningful comparison of the odds ratio with that of the other variables.

TABLE 3—Variables Explaining Not Eating for 1 or More Days among Home-Delivered Meal Clients in Extended Model for 1985 to 1986 survey (n = 1431)

	Percentage of Sample	Regression Coefficient	Odds Ratio	95% CI for Odds Ratio	
Constant		−2.15			
Minority living outside NYC	2	1.33	3.77	1.70	8.37

Minority living in NYC	3	1.16	3.19	1.59	6.43
Receiving Medicaid	21	0.47	1.60	1.15	2.25
Age 80 years or older	42	−0.49	0.61	0.45	0.84
Female living alone	45	−0.10	0.90	0.63	1.30
Male not living alone	16	−0.28	0.75	0.46	1.23
Male living alone	16	0.34	1.41	0.89	2.22
Number of health problems[a]	1.9	−0.04	0.92	0.71	1.20
Having cancer	11	0.41	1.51	1.00	2.28
Being mobile with aids	41	−0.03	0.97	0.71	1.32
Being chair- or bed-bound	5	0.52	1.68	0.94	3.01
Having nausea	16	0.36	1.44	0.99	2.09
Having difficulty swallowing	12	0.43	1.54	1.03	2.30
Having diarrhea	12	0.41	1.51	1.01	2.26
Loss of appetite	34	0.91	2.48	1.83	3.37
Receiving food from food pantry	5	0.69	2.00	1.14	3.49

Note. CI = confidence interval; NYC = New York City. The likelihood ratio chi-square statistic for comparison with the model having only the constant was 153.36 (17 *df*). The likelihood ratio chi-square statistic comparing this extended model with the original model for the 1985–1986 clients was 78.09 (5 *df*). The area under the ROC curve was 0.73. [a]The mean is shown (range, 0 to 4). The odds ratio and 95% CI were calculated for two times the regression coefficient; the factor of two corresponded to two standard deviations. This calculation allowed for a more meaningful comparison of the odds ratio with that of the other variables.

Acknowledgments

This research was funded in part by the New York State Department of Health. We are grateful for the interest and help of Janice Dodds, former Director of Nutrition Surveillance, New York State Department of Health, and Dorothy Diggins, New York State Office for Aging, who were instrumental in the initiation and support of this study. We especially thank the dedicated people in the county and local program offices for their fine work in collecting the data.

The South Karelia Air Pollution Study: Acute Health Effects of Malodorous Sulfur Air Pollutants Released by a Pulp Mill

Tari Haahtela, MD, Olli Marttila, MSc, Vesa Vilkka, MD, Paavo Jäppinen, MD, and Jouni J. K. Jaakkola, MD

ABSTRACT

We evaluated the acute health effects of a strong emission of malodorous sulfur compounds released from a pulp mill in South Karelia, Finland. The 24-hour ambient air concentrations of hydrogen sulfide for the two emission days were 35 and 43 $\mu g/m^3$ (maximum 4-hour 135 $\mu g/m^3$). A questionnaire was distributed after the high exposure and later after a low exposure period to 29 households with 75 subjects living in the nearby community. During the high exposure, 63% of the respondents reported experience of at least one symptom compared to 26% during the reference period. Every third participant reported difficulties in breathing. In the 45 subjects responding to both questionnaires more eye, respiratory and neuropsychological symptoms occurred during the exposure compared to the reference period. The strong malodorous emission from a pulp mill caused an alarming amount of adverse effects in the exposed population. (*Am J Public Health.* 1992;82:603–605)

Introduction

Large populations in northern Europe and North America are often or constantly exposed to malodorous sulfur air pollutants such as hydrogen sulfide (H_2S), methyl mercaptan (CH_3SH), and methyl sulfides produced by the paper and pulp industry. The knowledge of the adverse effects of these pollutants is sparse, although people living in the neighborhood affected commonly complain of discomfort and express concern about the health effects.

A cluster of paper mills producing wood pulp is located in South Karelia, in southeastern Finland. The two sulfate pulp mills, located in the small city of Imatra (33 000 inhabitants), were, in 1989, estimated to emit annually 2800 tons of H_2S into the air. The annual mean (2 $\mu g/m^3$) concentration of sulfur dioxide (SO_2) is low because of the use of natural gas as the source of industrial energy.

During 2 days in September 1987, a strong emission, with H_2S as the major component and mesityloxide as a minor component, was released from one of the two pulp mills, exposing the local population to intensive catty odor for the 2 days. We evaluated the acute health effects of the emission by comparing the occurrence of symptoms during the high-exposure period and 4 months later during a low-exposure period.

Material and Methods

During the introduction of a new processing technique, a strong malodorous emission was released from the pulp mill using the sulfate method for production, and increased concentrations of H_2S were measured for 2 days at our monitoring station located in a nearby community about 1 km southeast of the source of exposure. The H_2S exposure was measured by absorbing the air sample to cadmium hydroxide.[1] The 4-hour concentrations of H_2S during the high exposure were, on the average, 4 to 5 times higher, and a maximum of 20 times higher, than the levels before and after the peak emission, during which there was inversion of the air and no wind (Figure 1). The highest 4-hour concentration of H_2S, 135 $\mu g/m^3$, was measured at 2 AM. The 24-hour averages for the 2 days were 35 and 43 $\mu g/m^3$.

During the peak emission of malodorous sulfur compounds, the mean 1-hour concentration of SO_2 was only 3 $\mu g/m^3$. It was not possible to measure mesityloxide in the ambient air. Mesityloxide is produced inside pulp mills under the same kinds of conditions that occurred during the peak emission. The presence of mesityloxide was recognized in the air by its characteristic catty odor.

A reference period of 2 days was chosen about 4 months later, in January 1988. During the 2 reference days no odor was sensed, and the concentration of H_2S was low (0.1 to 3.5 $\mu g/m^3$ for 4 hours). The SO_2 concentration was low, 3 $\mu g/m^3$, as during the high-exposure period.

An open-ended questionnaire was distributed 10 days after the high exposure to all 29 households of the nearby community; 66 (88%) of a possible 75 subjects responded. Six subjects were excluded because of missing information, leaving 60 subjects: 44 adults (15 men and 29 women; mean age = 45 years and range = 17 to

85) and 16 children (9 boys and 7 girls; mean age = 7 years and range = 1 to 15). The respondents were asked to describe the symptoms they had experienced during the days of peak exposure, without mention of the exceptionally high emission of pollutants or what kinds of symptoms the emission may generate. Parents responded on behalf of their children.

An identical questionnaire was distributed to the same households 4 months later. The link of this reference questionnaire to the first inquiry was not revealed. The response rate was 79%, no data had to be excluded, and 66 persons were included in the analyses. The effect of confounding was controlled by studying the intraindividual difference in the symptoms in the subpopulation of 45 subjects who responded to both questionnaires. The statistical significance of the difference in the occurrence of the symptoms during the high-exposure and reference periods was assessed by a χ^2-test and McNemar's test.[2]

Results

The unadjusted prevalences of the different symptoms in the two population samples are given in Table 1. Large proportions of the participants reported breathlessness (35%) and mental symptoms (10%) during the high-exposure period, while no such symptoms were indicated during the reference period. The prevalence of eye symptoms (22% vs 2%), cough or pharyngeal irritation (15% vs 5%), and nausea (14% vs 3%) were also significantly larger during the high exposure. However, nasal symptoms (8% vs 20%) were more common during the reference period than the high-exposure period, although the difference was not significant. Altogether, 63% of the subjects reported experience of at least one symptom during the high-exposure period compared with 26% during the reference period.

The presence of symptoms during the exposure and reference periods in the 45 subjects who responded to both questionnaires is shown in Table 2. Eye symptoms, cough or pharyngeal irritation, breathlessness, nausea, and headache were experienced more often during the exposure period than during the reference period. The difference was significant for breathlessness.

Discussion

The occurrence of the symptoms during the high-exposure period was large: Every third participant reported difficulties in breathing, and every fourth participant indicated irritation of eyes, headache, and nausea. Mental symptoms were also common. The prevalence of these symptoms was significantly larger than those during the reference period in the comparison of the two samples. The direction of the differences was similar in the intraindividual comparison of those who responded to both questionnaires, al-

though significance was not reached in all of the symptoms because of the smaller number of subjects than in the two-sample comparison. Interestingly, more subjects reported nasal symptoms during the reference period than during the high-exposure period. A possible explanation is that breathing difficulties due to exposure were so prominent that attention was not paid to mild nasal symptoms. The highest 4-hour concentration of H_2S was 135 $\mu g/m^3$, which is nine times higher than the guideline in Canada (15 $\mu g/m^3$). There are no guidelines for ambient air H_2S in Finland.

The observed symptoms correspond to physiological effects of acute exposure of H_2S suggesting direct irritative effect on mucous membranes and eye conjunctivae, although in far smaller concentrations than described earlier.[3] Previously, we have observed an increased amount of eye and nasal symptoms and cough among subjects living in the most polluted area of Imatra.[4]

According to the World Health Organization (WHO) guideline values for H_2S, the highest acceptable half-hour concentration is 7 $\mu g/m^3$ for odor nuisance, along with a daily mean of 150 $\mu g/m^3$ for health hazards.[5] During the period of high exposure, the highest measured 4-hour concentration (135 $\mu g/m^3$) and 24-hour averages (35 and 42 $\mu g/m^3$) were well below the recommendation. These kind of emissions are rather commonplace and are always possible wherever wood pulp production takes place. It seems likely that the WHO guideline value of 150 $\mu g/m^3$ for H_2S is too high and does not provide prevention from adverse health effects. Furthermore, the presence of other pollutants should be taken into account, because H_2S is rarely the only hazardous component of air pollution. □

The Epidemiology of Low Back Pain in an Adolescent Population

ABSTRACT

We assessed the prevalence of low back pain (LBP) in a cohort of 1242 adolescents (aged 11 through 17) currently participating in a 4-year prospective study of medically treated injuries. Overall, 30.4% of the adolescents reported LBP. The impact of LBP in adolescents was considerable, with one third resulting in restricted activity and 7.3% seeking medical attention. Life-table analysis demonstrated that by age 15, the prevalence of LBP increased to 36%. There were few differences by gender or race. These results suggest that LBP in adolescents is a serious public health problem. (*Am J Public Health.* 1992;82:606–608)

Todd L. Olsen, MS, MPH, Robyn L. Anderson, MS, MPH, Stephen R. Dearwater, MS, Andrea M. Kriska, PhD, Jane A. Cauley, DrPH, Deborah J. Aaron, MS, and Ronald E. LaPorte, PhD

Introduction

Recent figures indicate that 70% to 80% of the general population will suffer from low back pain (LBP) at some point in their lives.[1–3] Research on LBP has focused primarily on occupational studies in adult populations. Little is known about the development of LBP in children. The epidemiology of LBP in adolescence is of particular importance, as LBP may occur initially during this time and may foreshadow the subsequent severe, chronic morbidity seen in adulthood.

There are only limited data on the prevalence of LBP in adolescents, probably because the disorder in this age group has been thought to be rare. Turner and colleagues[4] found that less than 2% of all children under age 15 presented with LBP at an orthopedic practice. Additionally, Grantham,[5] a school doctor in Northamptonshire, United Kingdom, found that 11.5% of his adolescent male students were seen because of LBP. In contrast to these clinical studies, two school-based studies from Europe have shown that backache may be quite common in this age group. Specifically, Balague et al.[6] found that 27% of 1715 Swiss school pupils complained of LBP as assessed from a validated questionnaire. A similar prevalence of LBP (26%) was found in English school pupils studied by Fairbank et al.[7]

From these few studies, the prevalence of LBP in adolescents in the United States is not clear, nor are the demographic factors associated with the disorder. In addition, there is no information concerning when the first symptoms of LBP appear in populations. Therefore, the proposed research evaluated for the first time in the United States the epidemiology of LBP in a biracial population of adolescents.

Population and Methods

Data on LBP were collected as part of an ongoing prospective population-based investigation of the epidemiology of adolescent injuries. The population undergoing injury surveillance consisted of 1246 (89%) of the 1400 seventh through ninth graders from an urban school district in Allegheny County, Pa. The demographic characteristics of the school district were virtually identical to those of the county.

LBP was ascertained using a modified questionnaire of Fairbank et al., a copy of which is included in the Appendix. The questionnaire was designed to identify any occurrence of LBP in adolescents, its severity, age of onset, recurrence, activity limitation, and medical treatment. The reliability of the survey has been found to be high, with an 84% consistency rate over 6 months.[2]

Results

Ninety-nine percent (1242/1246) of the students participating in the study completed the LBP questionnaire. Table 1 presents the demographic characteristics of the sample. There were 641 male and 601 female subjects 11 through 17 years of age, with an average age of 13.6 years. This represented students in grades seven (32.7%), eight (33.0%), and nine (34.3%).

A surprisingly high percentage, 30.4% (95% confidence interval [CI] = 28.7, 32.2) of the children reported ever experiencing low back pain (Question 1). Twenty-two percent (95% CI = 20.5, 23.0) of the children reported experiencing LBP within the previous 12 months (Question 3). Seven percent (95% CI = 6.9, 7.7) of those who reported LBP sought medical attention at least once (Question 5). There was a greater prevalence of LBP leading to medical attention for girls, 8.0% (95% CI = 7.4, 8.7) vs boys,

Todd L. Olsen, Robyn L. Anderson, Andrea Kriska, Jane A. Cauley, Deborah Aaron, and Ronald E. LaPorte are with the Department of Epidemiology, University of Pittsburgh, Pittsburgh, Pa. Stephen Dearwater is with the Sports Medicine Institute, University of Pittsburgh Medical Center, Pittsburgh, Pa.

6.7% (95% CI = 6.2, 7.2). In addition, 8.8% (95% CI = 8.3, 9.3), of the students indicated that the back pain was sufficiently severe to force them to miss school or keep them from playing sports (Question 4).

Figure 1 presents the prevalence of LBP by age and race. The only difference in LBP prevalence when examined by race occurred at age 15 where Blacks had significantly higher rates than Whites (47% vs 31%, $P < .05$).

Life-table analysis, as seen in Figure 2, demonstrated that by age 15 the likelihood of this cohort reporting LBP was 36%. There were no differences between boys and girls at any age. It should also be noted that LBP was rare under age 10. This finding can, however, be potentially related to subject recall. Low back pain was additionally analyzed by the hazard function in Figure 3, which can be interpreted as an age-at-onset incidence curve. There was a markedly accelerating incidence of LBP beginning at about age 10, with a continuously increasing risk through adolescence. By age 15, the risk of reporting the first occurrence of LBP was twice that of 12-year-olds, suggesting that the yearly risk of LBP increases dramatically during the teenage years.

Discussion

These results suggest that 1 in every 3 adolescents report experiencing LBP in their lifetime. If these results are extrapolated to the oldest age group, by age 15, 36% of the children would be expected to report the occurrence of LBP. Thus, LBP in adolescent children is a serious public health problem.

Our results are consistent with those seen in European population-based studies. Specifically, Fairbank et al.[7] and Balague et al.[6] found LBP rates of 26% and 27%, respectively.

Approximately one third of the self reported LBP was associated with activity limitations, with one in four of those suffering from LBP seeking medical treatment. Although this represents 3% and 2% of our adolescent cohort, respectively, the economic and public health implications are substantial when one considers the young age and recurrence potential. In a compreshensive review of the literature, Kelsey et al.[3] report that the first episode of LBP occurs most often between the ages of 20 and 40 years; however, these data have been based on recall of adults sometimes decades after the initial episode. Furthermore, costs associated with adult LBP presently exceed estimates of $16 billion.[8] Our results suggest that the initial onset and subsequent cost of LBP, may, in fact, occur early in youth.

There was a similar proportion of reported LBP in boys (30.7%) and girls (30.0%). As presented, it was unlikely that the LBP in girls was exclusively related to menstrual cycle because of the lack of sex differences. It is possible that potential determinants for LBP are thus similar for boys and girls.

The only observed racial differences in LBP were observed in the oldest adolescents. By age 15, blacks reported significantly higher prevalence rates of LBP than whites. There has been no other population based studies in children where it has been possible to examine race-specific prevalence rates.

Our findings, in accordance with other research, suggest that LBP in adolescents is potentially a very serious prob-

TABLE 1—Population Characteristics

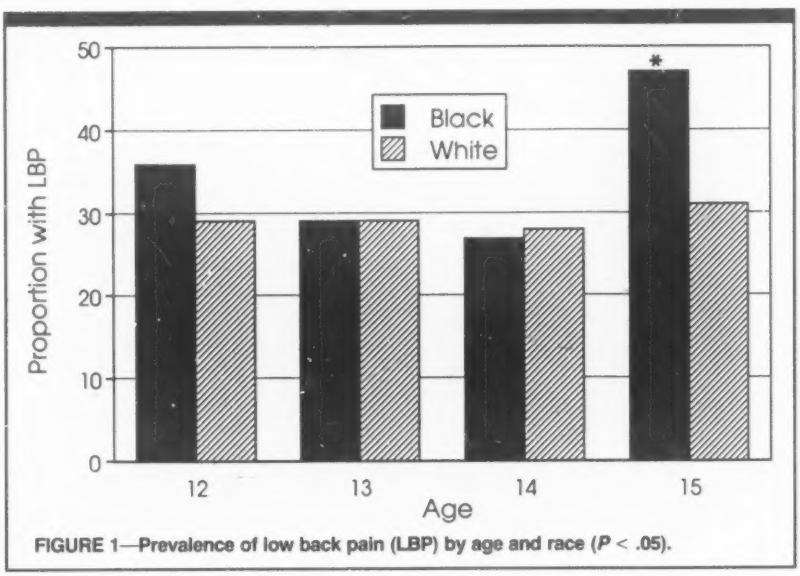

FIGURE 1—Prevalence of low back pain (LBP) by age and race ($P < .05$).

APPENDIX—Low Back Pain Assessment by Descriptive Questionnaire

1. Have you ever had pain or other trouble with the lower part of your back? (yes/no)
2. How old were you the first time that you had trouble with your back? (__ years old)
3. Have you had pain or other trouble with the lower part of your back within the last 12 months? (yes/no)
4. Has your back pain ever stopped you from going to school or playing sports? (yes/no)
5. Have you ever seen your doctor about back pain? (yes/no)

lem. Future research in adolescents must address the etiology, associated risk factors, and severity and the degree to which these predict subsequent recurrence of LBP. This may help to identify those adolescents who are at greatest risk for developing debilitating LBP in adulthood so that preventive measures can be undertaken to reduce its occurrence. □

Call for Abstracts on Chronic Disease Prevention and Control

The Centers for Disease Control, the Association of State and Territorial Health Officials, and the Association of State and Territorial Chronic Disease Program Directors announce the Seventh National Conference on Chronic Disease Prevention and Control to be held at the Salt Lake Hilton Hotel in Salt Lake City, Utah, October 21 to 23, 1992. The Utah Department of Health will host the conference, which is open to the public.

Abstracts are being solicited and will be considered for concurrent oral presentations or poster sessions dealing with (a) assessment and evaluation, (b) chronic disease epidemiology, and (c) program applications.

Deadline for submission is Friday, May 1, 1992. For more information, please contact Jack Friel, NCCD PHP, Mail Stop K-43, Centers for Disease Control, Atlanta, GA 30333. Tel: 404/488-5390; Fax: 404/488-5962.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Barrier Contraceptives and Sexually Transmitted Diseases in Women: A Comparison of Female-Dependent Methods and Condoms

Michael J. Rosenberg, MD, MPH, Arthur J. Davidson, MD, MSPH, Jian-Hua Chen, MD, MSPH, Franklyn N. Judson, MD, and John M. Douglas, MD

ABSTRACT

Introduction. Most efforts at sexually transmitted disease (STD) protection center on condom use, but little is known about how condoms compare with other barrier methods, particularly those controlled by women.

Methods. To evaluate the effect of different barrier contraceptives on the prevalence of STDs and other vaginal infections, we retrospectively studied 5681 visits by women to an urban STD clinic.

Results. As compared with women using no contraceptive or with tubal ligations, women using the contraceptive sponge or diaphragm had at least 65% lower rates or infection with *Neisseria gonorrhoeae* and *Trichomonas vaginalis,* while condom users had 34% and 30% lower rates, respectively. For *Chlamydia trachomatis,* the reduction was 13% among sponge users, 72% among diaphragm users, and 3% among condom users, although these differences were not significant. When compared with women using condoms, women using female-dependent methods (sponge or diaphragm) had significantly lower rates of both gonorrhea and trichomoniasis. Vaginal candidiasis was more common among women using diaphragms but not other barrier methods, while rates of bacterial vaginosis were similar among all groups.

Conclusions. Women using the contraceptive sponge or diaphragm experience protection from STDs to a greater extent than those relying on condoms. Female-dependent barrier contraceptives should receive more attention in STD risk-reduction programs. (*Am J Public Health.* 1992; 82:669–674)

Introduction

In 1988, an estimated 12 million new cases of sexually transmitted diseases (STDs) occurred in the United States. Three quarters of these were accounted for by three diseases—chlamydia (4 million cases), trichomoniasis (3 million), and gonorrhea (1.8 million).[1] The realizations that most STDs have increased over the past decade, that complications of these infections cost billions of dollars each year, and that certain STDs are risk factors for transmission of human immunodeficiency virus (HIV) have spurred efforts to identify effective means of preventing their spread. Such efforts are particularly important for women, since they suffer the greatest consequences of bacterial STDs in the form of pelvic inflammatory disease, ectopic pregnancy, and infertility.

Women who use barrier contraceptives (spermicides, the contraceptive sponge, condoms, or diaphragms) have generally lower prevalence rates of STDs than women using other forms of contraception or no contraception.[2] Clinical studies, however, show variable degrees of reduction in gonorrhea, nongonococcal urethritis, and chlamydia among users of condoms[3–8] and spermicides[6,7,9–14] as compared with contraceptive nonusers. This work is supported by laboratory evidence that intact condoms are impermeable to virtually all sexually transmitted organisms studied[15,16] and that spermicides effectively kill a variety of STD pathogens,[9] including HIV.[17]

Because the manner in which contraceptives are used in daily practice is an important determinant of protection against STDs, observational studies are an important reflection of protection applicable to large numbers of people. Two such studies indicated that female-dependent methods (spermicides and/or diaphragms) provided protection at least as strong as that afforded by condom use against gonorrhea.[6,18] These studies are limited, however, by absent or incomplete information on STD risk factors. In addition, most evaluated a single outcome, and all were performed before 1987, when prevention messages were not as widespread as they are today. To address these limitations, we studied the relationship between recent use of three popular forms of barrier contraceptives and prevalence of common STDs and vaginal infections among women attending a large urban STD clinic.

Methods

The Denver Metro Health Clinic for STDs serves 1.6 million residents of the Denver standard metropolitan statistical

area. Women may visit the clinic because of genitourinary symptoms or concerns over STDs or may be referred by their partner, STD health investigators, another clinic, or the police department after an arrest for prostitution.

The study involved review of charts of women visiting the clinic for a new problem. Each woman was interviewed regarding demographic and behavioral information, including the single contraceptive that was used most frequently during the previous month. Routine laboratory evaluation of women included cervical culture for *Neisseria gonorrhoeae* and evaluation of vaginal fluid for pH and by microscopic examination. During certain periods, cervical culture for *Chlamydia trachomatis* was also performed as part of the routine examination; only visits by women during these periods were considered for the analysis of *C. trachomatis*.

Cultures for *N. gonorrhoeae* and *C. trachomatis* were carried out by conventional techniques.[19,20] The presence of *Trichomonas vaginalis* was detected by microscopic examination of saline suspension of vaginal secretions. A diagnosis of candidiasis was established by the presence of a characteristic curdy white vaginal discharge and/or the microscopic identification of fungal hyphae in vaginal discharge after treatment with potassium hydroxide. Bacterial vaginosis was diagnosed in women with symptoms of vaginitis by conventional diagnostic criteria[21] in the absence of another explanation for the symptoms.

After excluding women who used oral contraceptives (n = 1944), intrauterine devices (n = 173), or "other" (n = 134), or who had undergone a hysterectomy (n = 424), patients were divided into groups according to contraceptive used. For each outcome, women using one of three types of barrier contraceptives (sponge, diaphragm, or condom) were compared with a combined nonbarrier control group of women with a tubal ligation or using no contraception. Ninety percent test-based confidence limits[22] were used for the outcomes of gonorrhea, chlamydia, and trichomoniasis, consistent with the suggestion of protection from previous work.[3-14] Ninety-five percent confidence intervals (CIs) were used for outcomes of candidiasis and bacterial vaginosis, about both of which there is little prior information. CIs that exclude 1.0 are significant at the level of $P < .05$ (one-sided P values for 90% CIs, two-sided P values for 95% CIs).

Stepwise logistic regression analysis[23] was used to identify confounders[24] and to test for interaction.[25] This method retains those factors that change the odds ratio by 10% or more, although some variables were retained because of their clinical importance.

Results

Between January 1, 1987, and December 31, 1988, there were 5681 visits for the evaluation of a new problem by women using the contraceptive sponge, diaphragm, condom, tubal ligation, or no contraceptive. These visits occurred among 4162 women, of whom 73% had one visit during the study period, 16% had two visits, 6% had three visits, and 4% had four or more visits. *C. trachomatis* was the most prevalent infection (13.6%), followed by *Candida* (12.2%), *N. gonorrhoeae* (11.9%), *T. vaginalis* (11.1%), and bacterial vaginosis (10.7%). The majority (76%) of visits were by women using no barrier (tubal ligation or no contraceptive); condom use was reported at 18% of visits, diaphragm use at 4%, and the contraceptive sponge at 2% (Table 1). The women were predominantly young, heterosexual, and sexually active.

The most marked reductions were found among sponge users and diaphragm users for both gonorrhea (relative risk [RR] = 0.22 and 0.19, respectively) and trichomoniasis (RR = 0.23 and 0.20) (Table 2). A lesser but also significant degree of reduction was found among condom users for gonorrhea (RR = 0.70) and trichomoniasis (RR = 0.86). While both sponge and diaphragm users had a reduced prevalence of chlamydia (RR = 0.58 and 0.18), neither reduction was statistically significant given the fewer individuals evaluated. Condom users, in contrast, had no reduction in the prevalence of chlamydia (RR = 0.99). Adjustment for multiple risk factors altered the results little, slightly reducing estimates of protection for sponge and diaphragm users and minimally increasing those for condom users. Adjustment had the most marked effect when comparisons involved the fewest subjects (sponge users) and the least effect in the group with the greatest number of subjects (condom users), particularly for outcomes that were infrequently assessed (i.e., chlamydia).

For candidiasis and bacterial vaginosis, the only significant difference was found among diaphragm users, who had more candidal infections than did the control group (Table 2). Risk estimates for other contraceptive groups were close to 1.0, with 95% CIs that encompassed 1.0.

Because of the similarity of findings among women using the sponge and diaphragm, we combined these groups to compare female-dependent barrier methods with condoms. Women using female-dependent methods had significantly fewer infections with *N. gonorrhoeae* and *T. vaginalis* than did women who relied on their partners' use of condoms (Table 3). The combined group also had lower rates of *C. trachomatis* and bacterial vaginosis, although neither difference was statistically significant. Sponge and diaphragm users had a significantly higher prevalence of candidiasis than did condom users.

The minimal difference between unadjusted (crude) and adjusted risk estimates for the condom group indicates a lack of substantial confounding by factors included in the model. Where adjusting made the greatest difference, the change may reflect an unstable odds ratio rather than the adjusted estimate being a more accurate indicator. In addition, there were no meaningful changes in risk estimates when subgroups of women were analyzed according to whether women with at least one new partner in the past month were excluded, or whether only first visits during the 2-year study interval were considered (data not shown). We found no evidence of interaction between factors in the model.

Among all risk factors considered, contraceptives were the most consistent predictor of presence or absence of the STD outcomes studied (Table 4). Other risk factors studied had variable effects, depending on the outcome. For example, contact with a known or suspected STD carrier was a strong risk factor for gonorrhea, but not for trichomoniasis or chlamydia. The high number of significant associations for gonorrhea may, in part, reflect the greater number of subjects included in these analyses.

Discussion

Women using the contraceptive sponge, diaphragm, and condom all had significantly lower rates of infection with *N. gonorrhoeae* and *T. vaginalis* than did a control group of women who used no contraceptive or with tubal ligations. Each barrier contraceptive group also had lower rates of *C. trachomatis* infection, although the smaller number of cases limited the precision in defining this relationship. Furthermore, for gonorrhea and trichomoniasis, a greater reduction was found among

women using the contraceptive sponge or diaphragm than those using condoms. For the outcome of candidiasis, which might be considered an adverse consequence of use of spermicide-containing barrier contraceptives,[10] there was a significant elevation among diaphragm but not sponge users.

Our finding of lower disease rates among women using barrier methods is in agreement with previous literature. A study involving chart review of health maintenance organization patients found users of vaginal spermicides to have an 87% reduction in gonorrhea,[7] while a cross-sectional evaluation at an STD clinic found a 61% reduction.[12] Clinical trials of the contraceptive sponge[10,13] and of a vaginal spermicidal jelly[11] have reported reductions of 10% to 69% for gonorrhea and 21% to 40% for chlamydia.

Our work also indicates that the two female-dependent barrier methods investigated, the contraceptive sponge and diaphragm, may provide better user effectiveness against various STDs than condoms. Such a finding was suggested by an earlier case-control study that found a 13% reduction in gonorrhea among condom users, a 10% reduction among users of spermicides alone, and a 55% reduction among women who used diaphragms in conjunction with spermicides.[6] Other studies found significant reductions of 64% for gonorrhea and 97% for chlamydia among diaphragm users, but reductions among condom users were reported only as nonsignificant.[18] Trichomoniasis was found to be 80% lower in spermicidal foam users but only 25% and 22% lower in diaphragm and condoms users, respectively.[26] We found a significantly lower prevalence of gonorrhea and trichomoniasis among users of both diaphragms (which we assume were used with spermicides) and sponges than among users of condoms that persisted after adjustment for multiple STD risk indicators.

There is less information regarding the relationship of barrier contraceptives and candidiasis, trichomoniasis, and bacterial vaginosis. Candidiasis was found nearly three times more frequently among contraceptive sponge users than in women not using a vaginal contraceptive in a clinical trial conducted among prostitutes in Thailand.[10] These women used the sponge nearly continuously until they either became infected with gonorrhea or chlamydia or completed a 3-week period. In contrast, most sexually active women are likely to use barrier contraceptives only intermittently, perhaps allowing a greater opportunity for normal vaginal bacterial flora to reestablish colonization. This possibility is suggested by our finding of an increased rate of candidiasis among diaphragm but not sponge users, as well as other studies that found minimal or no change in candidiasis among spermicide users.[25,27,28]

The few studies of bacterial vaginosis indicate modest, nonsignificant reductions among spermicide users.[21,28] Our study, which is substantially larger, indicates a virtually identical rate of bacterial vaginosis among users of sponges, diaphragms, and condoms and among the control group, suggesting that none of these barrier methods are effective in preventing this syndrome and that spermicides have little effect on the alteration in vaginal flora associated with bacterial vag-

TABLE 3—Risk of Clinical Outcome for Users of Contraceptive Sponge or Diaphragm as Compared with Users of Condoms

Outcome	Odds Ratio Crude	Odds Ratio Adjusted[a]	95% Confidence Interval
Gonorrhea	0.28	0.45	0.22–0.92*
Trichomoniasis	0.24	0.33	0.17–0.64*
Chlamydia	0.33	0.84	0.25–2.81
Bacterial vaginosis	1.03	0.88	0.59–1.31
Candidiasis	1.60	1.62	1.15–2.28*

[a]Adjusted for age, race, number of sexual partners in previous month, number of new partners in previous month, total lifetime partners, symptoms, reason for visit, and history of chlamydia, gonorrhea, or trichomoniasis.
*$P(2) < .05$.

inosis. Our finding of a reduced rate of trichomoniasis is similar to that from a cross-sectional study[29] and less marked than the modest, nonsignificant decrease for participants in a placebo-controlled clinical trial.[28]

The size and design of this study provide several advantages over previous efforts. First, our data reflect day-to-day, subject-reported use in a nonmonitored environment. Such user effectiveness, as differentiated from efficacy in optimal circumstances (method effectiveness), is an important consideration in judging usefulness in STD prevention efforts. Second, the large number of women and three different STD outcomes analyzed allows a more comprehensive evaluation of the effect of individual contraceptives, including a recent introduction, the contraceptive sponge, on a range of outcomes. Finally, the detailed information on STD risk indicators provides assurance that the observed relationships are not distorted by STD risk that may have differed between groups of women using different contraceptives.

Although we had extensive information on factors related to risk of STD acquisition, there may be other unquantified factors related to STD risk or contraceptive choice for which we were unable to control. For example, we do not know how reliably the STD risk factors and markers we measured characterized risk profiles of women or their partners and whether unmeasured factors might have systematically differed between contraceptive user groups. However, the consistency of factors associated with STDs in this study (age, race, reason for visit, number of new sexual partners, and total number of sexual partners) and other studies and the relatively small change in risk estimates after adjusting for these factors suggest a lack of substantial bias.

Misclassification error may have been introduced by the lack of information on concurrent use of more than one contraceptive method or inconsistent use of contraceptives. Also, we evaluated only a relatively short time period (1 month), and women may have become infected prior to this time. This may be particularly important for an infection such as *C. trachomatis,* which may have a prolonged asymptomatic carrier state. If such errors

were common, they could cause an over- or underestimate of true relative risk, depending on the sequence, the effectiveness of each method, and how each contraceptive was used. We suspect that simultaneous use of more than one method is probably rare, based on a previous study of contraception and gonorrhea that found that only 2% of women used some form of spermicides in addition to condoms.[6] If women more frequently used multiple methods, and the use of multiple methods were approximately equal in different user groups, then the differences reflected in our study would underestimate the true magnitude of protection. Similarly, inconsistent use of a single method would also underestimate the reduction of risk provided by barrier contraceptives, with the magnitude proportional to the degree of nonuse. Of interest, however, is the finding during a recent clinical trial of spermicides that only slight reduction of risk occurred with increasing compliance.[11] This observation suggests that protective measures are more likely to be used during high-risk encounters and is supported by our finding of no change in risk after women with a new partner in the previous month were eliminated from the analysis.

An additional source of bias due to disease ascertainment could have arisen from the fact that clinicians were aware of the contraceptive being used. However, since diagnostic studies performed were not influenced by the contraceptive used, this factor is unlikely to have influenced the results. Finally, it is also possible that women using different contraceptive methods may be more likely to seek STD care at other health care facilities. If such care were more common among women using the contraceptive sponge or diaphragm, our findings would overestimate the associated degree of reduction.

The difference in STD rates between female- and male-dependent barriers may be partially due to different frequencies of use. The disparity between the high levels of condom efficacy in the laboratory[15] and the results of this and other studies suggests that condoms are often used improperly and/or intermittently. This finding is consistent with reports of low condom use, even in high-risk groups.[30-35] A recent review demonstrates underuse of condoms, particularly among individuals at high risk such as persons with multiple sex partners and those previously treated for an STD.[36]

Our data suggest that efforts to help control STDs by use of barrier contraceptives should be oriented toward women to a greater extent than in the past. STDs can be transmitted more easily from men to women than vice versa,[5,37,38] and women experience more frequent and serious complications. Although STD prevention efforts have emphasized condoms to the virtual exclusion of other barrier methods, there is a need to identify methods that women can use independently of their partners. This is particularly true for those at highest risk for STDs, since these women, often young or socioeconomically disadvantaged, may lack the interpersonal skills necessary to negotiate the use of condoms. Identifying methods that are available without prescription is especially important for adolescents, who are at highest risk of pregnancy and STDs. Newer spermicidal preparations, such as the contraceptive sponge, may help STD prevention efforts because of their better acceptability as compared with other vaginal preparations (A. C. Nielsen, Drug and Food Index data, unpublished), and thus their greater likelihood of use.

The urgency of the STD problem and the incomplete information about the value of female-dependent methods[39,40] indicate the importance of further investigations to confirm and extend our findings. Most immediately, studies are needed that will provide more complete information about contraceptive use and STD risk indicators of women and their sexual partners. While prospective studies will generate useful data, it must be recognized that the intensive intervention that occurs in such studies will result in contraceptive use patterns that are unlikely to be achieved in everyday use. Thus, observational studies, with emphasis on careful validation of STD risk and contraceptive use, will remain a vital component of such needed research. □

TABLE 4—Odds Ratios for Factors Related to Clinical Outcomes[a]

Pregnancy-Induced Hypertension in North Carolina, 1988 and 1989

David A. Savitz, PhD, and Jun Zhang, MB

ABSTRACT

Introduction. Pregnancy-induced hypertension (PIH) is a highly prevalent pregnancy complication with adverse effects on maternal and infant health. Epidemiologic research concerning its etiology is limited.

Methods. Birth records from North Carolina for the period 1988 through 1989 include an indication of the presence of PIH. The risk of PIH was examined in relation to several maternal characteristics and exposures, including reproductive history, demographic characteristics, and tobacco use during pregnancy. Risk ratio estimates, adjusted for confounders, were calculated contrasting PIH among exposed vs unexposed women.

Results. The overall risk of PIH was 43.1 per 1000 births, with multiple pregnancies, nulliparity, and advanced maternal age associated with markedly increased risks. Tobacco use was inversely associated with PIH, and Blacks and Whites were at virtually equal risk.

Conclusions. Problems in diagnosis and classification impede research in this area, with birth certificates limited in quality and breadth of information. Nonetheless, several patterns emerged that are worthy of further epidemiologic evaluation using more sophisticated designs. (*Am J Public Health* 1992;82:675–679)

Introduction

Pregnancy-induced hypertension (PIH) is among the most common pregnancy complications, with a cumulative incidence estimated as high as 7%.[1,2] PIH is associated with a substantial increase in growth retardation and preterm birth and threatens the life of the mother if untreated.[3] Classification of PIH remains controversial, but most authorities recognize that (1) preexisting hypertension and hypertension developing during labor are distinct from hypertension developing during pregnancy[4] and (2) preeclampsia, in which the blood pressure elevation is accompanied by proteinuria or edema, is distinct from gestational hypertension alone.[5] Nonetheless, the common occurrence of edema in late pregnancy and frequent difficulty in accurately separating preeclampsia from isolated gestational hypertension[4] make PIH a suitable entity for etiologic research, while recognizing that there are likely to be heterogeneous subcategories present.[6]

There has been limited research into the etiology of PIH, in spite of its frequency. Primiparas are known to be at markedly greater risk of preeclampsia than multiparas.[7] Women who smoke cigarettes have been reported to show a reduced risk of preeclampsia.[8,9] Elevated blood lead levels,[10] exposure to organic solvents,[11] lack of leisure-time physical activity early in pregnancy,[12] male fetuses,[13] low levels of calcium intake,[14] use of barrier contraceptives,[15] and young maternal age[16] have all been reported to increase the risk of PIH or preeclampsia, but these observations await corroboration or refutation. These clues deserve follow-up in focused studies, yet additional analyses that simply describe the patterns of occurrence in defined populations are also needed. Even such basic questions as the presence of racial differences in risk have not been resolved.[16] The modification of the North Carolina birth certificate in 1988 to include a checklist item for PIH, as well as several risk factors of potential interest (e.g., cigarette smoking), provides an efficient opportunity to examine patterns of PIH among women in the state.

Methods

Birth data for North Carolina for the years 1988 and 1989 were made available from the Center for Health and Environmental Statistics of the North Carolina Department of Environment, Health, and Natural Resources. A nurse or clerk in the hospital of delivery completes a certificate of live birth, which includes the usual array of demographic and residential information as well as a series of health conditions in check-box format. Three items from the birth certificate were used in this analysis: "hypertension, chronic"; "hypertension, pregnancy-associated"; and "eclampsia." This information is obtained from the medical record subsequent to delivery, with no formal quality-control procedures. Nonetheless, the clinical significance of these events makes them likely to be noted with some accuracy and prominence in the charts. Additional items used in the analysis were mother's age, moth-

er's education (in years), child's race (Black, White, other), child's sex, gravidity, parity, plurality (singleton, multiple birth), onset of prenatal care, tobacco use (cigarettes per day), gestational age, birthweight, weight gain during pregnancy, mother's residence (urban/rural, Coastal Plain vs other), and month and season of birth. Although information on alcohol use is requested, the very small number of women who were reported to have used alcohol during pregnancy (2.6%) suggests that the information is unsuitable for analysis.

Starting with a total of 199 651 live births to residents of North Carolina, women with missing data on PIH (n = 1636), preexisting hypertension present (n = 1869), or missing data on preexisting hypertension (n = 1636) were omitted (some women having more than one exclusion criterion), leaving 196 146 births for analysis. Risk among women with multiple as compared with singleton gestations differed markedly (80.6 per 1000 vs 42.2 per 1000, respectively), so women with multiple fetuses (n = 4527) were omitted from the main analyses. Absence of prenatal care was associated with reduced incidence of PIH (risks of 43.4 per 1000 and 22.4 per 1000, respectively). This pattern is presumably due to lack of opportunity for diagnosis, so that women with no prenatal care or with missing data on the onset of prenatal care were also omitted (n = 3975). This left 187 742 women (91 188 in 1988 and 96 554 in 1989) with information on PIH, known absence of preexisting hypertension, singleton gestations, and known initiation of prenatal care prior to delivery. PIH was defined as an indication of either "hypertension, pregnancy-associated" or "eclampsia." By definition, eclampsia must be preceded by preeclampsia.[4,6]

Risks of PIH were calculated per 1000 live births by dividing number of PIH cases by the total number of births in the stratum. We examined risk by calendar year, season, and geographic area in the state (focusing on urban–rural gradients and residence in the Coastal Plain). Demographic characteristics of interest included mother's race (White, Black, other), mother's and father's age, and mother's education. Races other than Black and White were too diverse for analysis, with small numbers of American Indians (2.5% of births), Filipinos (0.5% of births), and other Asian or Pacific Islanders (0.3% of births) and a smaller number of Chinese, Japanese, and Hawaiians.

Gravidity and parity were examined as indicators of reproductive history. Attributes of the present pregnancies included infant sex, timing of prenatal care onset, smoking during pregnancy, and potential consequences of PIH, including weight gain during pregnancy, gestational age at delivery, and birthweight.

Crude risks and risk ratios were calculated and adjusted odds ratios (ORs) obtained by Mantel-Haenzel adjustment and logistic regression.[17] PIH is sufficiently rare in this population (under 5%) that risk ratios and ORs would be similar in magnitude.

Results

For the period 1988 through 1989, the risk of PIH in North Carolina was 43.1 per thousand. Although lower than is often reported, this highly prevalent problem affected over 4200 women in the state each year. Risks were similar over the 2 years, with women delivering in the summer or fall at somewhat lower risk than those delivering in the winter or spring (40.3 and 46.1 per thousand, respectively).

Table 1 presents crude risk ratios and risk ratios adjusted for parity, with 95% confidence intervals (CIs). Dividing the state's population by community size yielded indications of a slightly higher risk in the most rural areas. Comparison of the Coastal Plain with the remainder of the state (data not shown) identified no gradient in PIH risk (adjusted OR = 1.0, 95% CI = 1.0–1.1).

A monotonically increasing risk of PIH was observed in relation to maternal age, with a twofold difference between the youngest (<20) and oldest (40+) mothers. Little difference was found across levels of maternal education, with a slight decrease in risk for women with 16 or more years of education. Blacks and Whites had similar PIH risks, with other races slightly lower. Infant sex was unrelated to PIH.

Gravidity and parity showed the most pronounced patterns: first pregnancies and births had double the risk of PIH compared with subsequent ones, with no evidence of a dose–response gradient after the first. Slight indications of a rising risk beyond parity 3 were observed. Among nulliparous women, there was no effect of differing gravidity: there was a relative risk of 1.0 for nulliparous women with previous pregnancies compared with those without previous pregnancies. Among mothers who received prenatal care, there were no differences in relation to the trimester in which care was begun.

Crude results for tobacco use showed an inverse gradient with PIH risk, which was diminished by adjustment for parity. Even after adjustment, however, there was a monotonically decreasing risk, with increasing amount smoked culminating in an adjusted risk ratio of 0.7 in women smoking 20 or more cigarettes per day.

Pronounced associations were found between PIH and reduced gestational age, reduced birthweight, and increased weight gain during pregnancy. These are not thought to be pertinent to the etiology of PIH; rather, they are presumably a reflection of the disease itself (increased weight gain due to edema) or the consequences of PIH (gestational age, birthweight).

Variables that were found to be associated with PIH (parity, mother's age, smoking during pregnancy) and others of a priori interest (race, mother's education) were examined simultaneously in a logistic regression model (Table 2). The results were generally consistent with the parity-adjusted risk ratios. Nulliparity remained strongly associated with increased risk. Blacks and Whites were indistinguishable in risk, with other races at lower risk. Older maternal age was associated with increased PIH risk, and education above 16 years was associated with decreased risk. Prenatal care onset was still essentially unrelated to PIH. Smoking's association with reduced risk was not affected by adjustment.

Separate logistic regression analyses for Blacks and Whites yielded similar patterns, except that the increased risk with advanced maternal age was stronger among Blacks and the benefits of high levels of education were stronger among Whites (Table 2).

Results were also compared for women of parity 0 vs women of parity 1+ (Table 2). The increased risk of PIH with increased maternal age was notably weaker among nulliparous women but was still apparent. Otherwise, the pattern of risk factors among the two parity groups was quite similar.

Discussion

The overall risk of PIH found in this analysis of North Carolina birth certificates (43.1 per 1000 singleton live births) is slightly lower than has been reported in the literature[2] but compatible with recent estimates of 26 per 1000 births for preeclampsia.[16] There is substantial confusion due to inconsistent terminology and diagnostic inaccuracies among preexisting

Note. All factors were included in the logistic regression model simultaneously, and thus adjusted for one another.

chronic hypertension, preeclampsia, and other forms of PIH that makes comparisons among studies difficult. Several papers have recently proposed standardized classification systems,[4-6] but at present these more refined classifications are not available for large populations.

The literature with which the patterns of PIH found in North Carolina can be compared is quite limited. An examination of patterns of hospitalized cases of preeclampsia found increased risk with young maternal age (in contrast to the opposite pattern reported here), although similar risks for Blacks and Whites were found in both studies.[16] The well-recognized increased risk of preeclampsia for nulliparas and plural gestations[7] was clearly identified in our data. Chesley cites "conventional wisdom" that Blacks are at greater risk of preeclampsia than Whites and that lower social class women are at greater risk than upper social class women, which he challenges for the absence of evidence.[7] The present data indicate the absence of such racial or social class differences, with a suggestion only of lower risk among women who are neither Black nor White.

The inverse association between cigarette smoking and PIH has been reported previously.[8,9] Marcoux et al. separated preeclampsia from other forms of PIH and found the strongest inverse association with preeclampsia, with risks of 0.8, 0.6, and 0.4 for smokers of less than 11, 11 to 20, and 20 or more cigarettes per day.[9] The present study found more modest reductions in risk of 0.9, 0.8, and 0.7 for similar smoking categories but combining all forms of PIH. Generally, the results of the two studies are similar given the weaker smoking gradient found by Marcoux et al. for PIH other than preeclampsia. The quality of smoking data on birth certificates is questionable, given the stigma associated with smoking during pregnancy, but nondifferential misclassification seems most probable with a resulting bias toward the null.[17] If the reporting were biased, one would expect overreporting for women with adverse outcomes (i.e., PIH) relative to women with uncomplicated pregnancies, opposite to the observed inverse association.

The limitations in the data should be acknowledged. The principal concern is in the undocumented process by which diagnoses of PIH are made. The process by which a woman comes to be documented on the birth certificate as having PIH involves many steps, including her entry into prenatal care, diagnosis by a physician, notation in the medical record, and transfer of that information to the birth certificate. Each step is potentially fallible, with underascertainment likely. Nonetheless, the overall risk of reported PIH seems reasonable, and the corroboration of previously recognized patterns by parity and cigarette smoking provides some reassurance regarding the quality of the data.

In spite of the virtually universal adoption of the new birth certificate format, there has been little work done to empirically assess the validity of its contents. To our knowledge, the only directly applicable study was a comparison in the state of Missouri between the risk of PIH based on the birth certificate item and the risk based on hospital discharge data (W. Schramm, written communication, May 1991). There were 42.5 cases per 1000 births based on hospital discharge data vs 36.1 cases per 1000 births based on the birth certificate information, resulting in a ratio of 0.85. This would suggest modest underascertainment on birth certificates, but the actual sensitivity and specificity of classification could not be estimated. Research is badly needed to evaluate the quality of specific items on the certificate so that researchers and health care planners can make appropriate use of what will soon be widely available data. Studies of pregnancy and delivery complications other than PIH in Washington State indicate that the check-box format yields more complete reporting than an open-ended format.[18]

A second limitation of this study is that it was not possible to separate PIH into true preeclampsia (hypertension with proteinuria or edema) and other forms of PIH for separate analyses. It was, however, possible to remove women with re-

ported chronic hypertension from the analysis. To the extent that the subtypes of PIH have distinct etiologies, the results reported here are diluted.

Finally, there was a limited array of information available from the birth certificate for analysis and, for at least some of the items, questions about data quality arise. Hypotheses regarding the role of nutrition and contraception, for example, could not be addressed at all. Alcohol use was judged to be inadequately reported for analysis, based on the rarity of reported use. Many of the demographic characteristics (mother's age, education, parity, etc.) are thought to be well reported. Although tobacco smoking as reported on the birth certificate has not been validated, a study in Missouri suggested that the aggregate levels are concordant with those obtained in the National Natality Survey.[19,20] The sample included in the National Natality Survey differs markedly from the North Carolina population with regard to race and marital status, but some reassurance of reasonable data quality is provided by the observation of similar patterns in the two sources (including comparable overall prevalence, reduced smoking during pregnancy with advancing age, and a marked reduction with increasing levels of education). Furthermore, recent analysis of North Carolina birth certificate data[21] revealed the usual pattern of reduced birthweight among smokers, providing additional assurance about the quality of that item.

The pattern of results supports further epidemiologic evaluation of this highly prevalent and etiologically mysterious condition. Perhaps the associations not found are as important as those that were: race and social class were virtually unrelated to risk except for a reduced risk among women of "other" races. This might suggest the absence of environmental influences, but the clear patterns by maternal age, parity, and tobacco use indicate otherwise. Weaker associations were found with season of birth (higher risks for winter and spring births) and increased risk with the most rural residence. With the recent availability of information on PIH in vital records, broader geographic areas should be examined to develop refined etiologic hypotheses in parallel with more focused studies of existing hypotheses. □

Acknowledgments

We would like to thank Paul Buescher, PhD, for his assistance in obtaining and interpreting the data and for his thorough and constructive review of the manuscript. We would also like to acknowledge the advice on disease classification provided by Watson Bowes III, MD.

The Transformation of American Midwifery: 1975 to 1988

Eugene R. Declercq, PhD

ABSTRACT

Background. The use of midwives is a natural solution to the problem of improving access to skilled perinatal services while lowering costs. The number of midwife-attended births has grown from 0.9% of all births in 1975 to 3.4% of all births in 1988. The purpose of the study was to determine how mothers served by midwives and the settings in which they are served have changed in that period.

Methods. The analysis is based on birth certificate data from 1975 to 1988 from the Natality, Marriage and Divorce Statistics Branch of the National Center for Health Statistics, Centers for Disease Control.

Results. Almost all of the growth (93.2%) in midwife-attended births from 1975 to 1988 was in hospitals; 87.3% of all births attended by midwives occurred in hospitals. Pronounced differences exist between mothers served by midwives in and outside of hospitals, and there are strong regional patterns in midwife attendance at birth.

Conclusions. Given the positive outcomes associated with midwifery practice, further research into the content of midwifery care is recommended. (*Am J Public Health.* 1992; 82:680–684)

Introduction

The practice of midwifery in the United States underwent certain changes between 1975 and 1988. (1975 is the first year for which data permit a detailed examination of midwife-attended births.) Midwives seem a natural solution to the problems of escalating costs and limited access in the US health care system.[1–3] Despite a heavy reliance on midwifery in many European countries with positive perinatal outcomes,[4–6] the use of midwives in the United States has been limited for a variety of reasons,[7] although there has been a significant recent growth in the number of nurse-midwives.[8] The last major national study to examine comparable data[9] was based on findings from 1978 and 1979, and several notable changes have been documented since that study. In this paper I examine the characteristics of mothers served by midwives, the settings in which midwives attend births (in or outside of hospitals), and regional variations in these factors.

Methods

All results presented are based on birth certificate data provided by the Natality, Marriage and Divorce Statistics Branch of the National Center for Health Statistics, Centers for Disease Control. With the exceptions of mother's education (73%) and Apgar scores (77%), the variables studied were reported in at least 99% of the cases. The basic comparisons will distinguish midwife-attended births, both in and outside of hospitals, from all births in the United States.

Results

Contemporary Midwifery Practice

Figure 1 illustrates the substantial growth in midwife attendance at births over the years from 1975 to 1988. Virtually all (93.2%) of the increase occurred in hospital births.[10] Overall, the proportion of all births that were attended by midwives increased from 0.9% in 1975 to 3.4% in 1988[10]; the number of midwife-attended births outside of hospitals decreased from 33.1% of all midwife-assisted births in 1975 to 12.7% in 1988. Because the birth certificate category of "midwife" as attendant includes both nurse-midwives and lay midwives, and the latter virtually never have hospital privileges,[11] the concentration of midwife practice in hospitals points to the growing dominance of nurse-midwives. These distinctions should become clearer with 1989 birth certificate data, which will, for the first time, distinguish between lay midwives and nurse-midwives.

Past research has found distinctions between the populations served by midwives in and outside of hospitals[9]; therefore, in the results shown in Table 1, both attendant and place of delivery have been controlled for. Midwives in hospitals serve mothers who are distinctly younger than average (48.3% are younger than 25 years, compared with 39.8% of all mothers), whereas midwives outside of hospitals at-

This paper was submitted to the Journal April 2, 1991, and accepted with revisions November 27, 1991.

tend mothers who are older than average (40.2% are older than 30 years, compared with 28.5% of all mothers). Midwife-attended births in hospitals differ somewhat from the norm in terms of proportion nonwhite. Mothers attended by midwives out of hospital are much more likely (94.6%) to be White. Midwives as a whole are also much more likely to serve foreign-born mothers (13.5% of all births are to foreign born mothers compared to 22.8% of midwife attended births); a significant proportion of those attended by midwives are Mexican-born mothers in Texas. Texas alone accounts for one third of all midwife-attended out-of-hospital births in the United States.

The findings on parity mirror those concerning age. Midwives attend mothers of much higher parity out of hospital (47.4% are parity 3+) than in hospital (29.4% are parity 3+) or all births (26.5%). Four states (California, Texas, Washington, and New York [outside of New York City]) do not report data on the education of mothers; therefore, the analysis of maternal education must be limited. However, the trends noted elsewhere are reaffirmed: mothers who are attended by midwives in hospitals are less well educated than average, and mothers who are attended by midwives outside of hospitals are generally better educated. The distinctions between hospital and out-of-hospital practice are even clearer with regard to marital status: 35.4% of midwife-attended hospital births are to unmarried mothers, and only 9.7% of out-of-hospital births attended by midwives are to unmarried mothers. This is a partial reflection of the difference in proportion of black mothers served in each setting.

Midwife-attended mothers typically begin prenatal care later than average, particularly in the case of out-of-hospital births. What is unknown, and clearly needs further study, is both the provider and the content of prenatal care delivered in these various settings. Mothers attended by midwives, both in and outside of hospitals, have low-birthweight babies (< 2500 g) at less than half the general rate. This is particularly true for babies born outside of hospitals, which is not surprising, given the characteristics of mothers who give birth outside of hospitals and past studies on birthweight and Apgar scores in out-of-hospital births.[12] There is little variance in low Apgar scores (< 7) among any of the comparison groups. Of the babies born out of hospital to mothers attended by midwives, 58.5% have a 1-minute Apgar score of 9 or 10. Of all births, 42.1% of babies achieve such a score; for midwife-attended hospital births, the figure is 45%. These findings are at least in part a function of careful risk assessment by midwives and referral of higher risk cases to doctors. The extent to which the nature of midwifery care plays a role in these results remains unclear.

State Analysis

Because the laws regulating midwives vary widely across states,[11,13] I an-

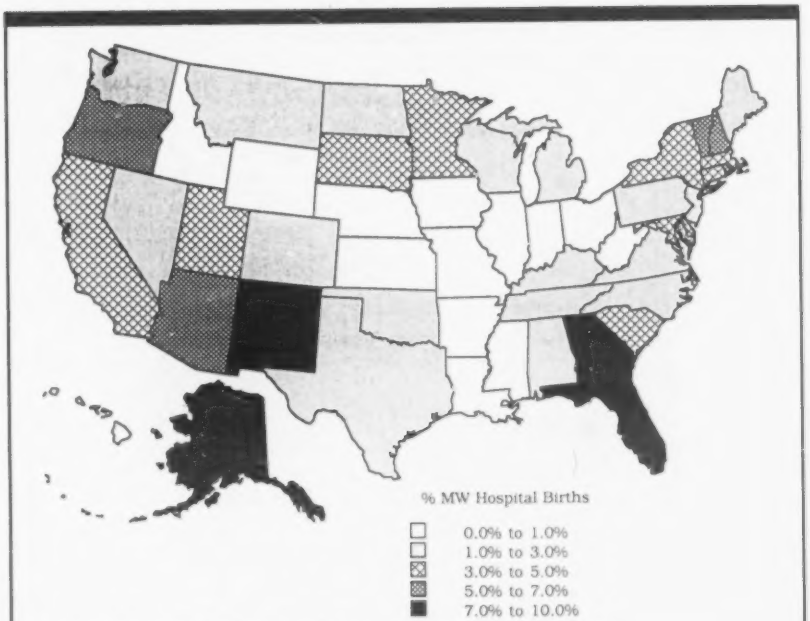

FIGURE 2—Midwife (MW)-attended hospital births by state, 1988.

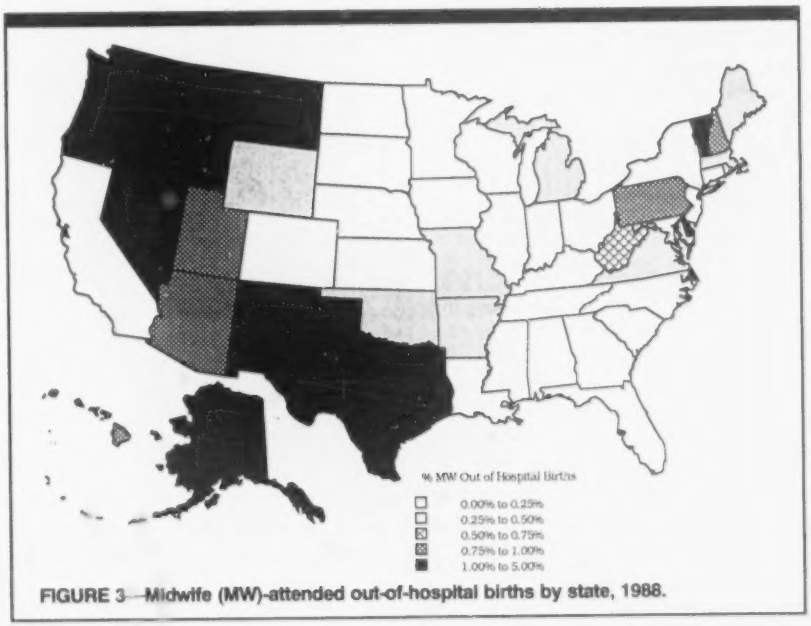

FIGURE 3—Midwife (MW)-attended out-of-hospital births by state, 1988.

alyzed interstate differences. Figure 2 illustrates regional variations in midwife-attended hospital births in 1988. Midwife attendance at hospital births was concentrated along the coasts and in the upper Midwest. Figure 3 also shows a strong regional pattern in the prevalence of midwife-attended out-of-hospital births: it is largely a Western phenomenon. Eight of the nine states where midwife-attended out-of-hospital births account for more than 1% of all births are located west of the Mississippi. In only four Eastern states are more than 0.5% of all births out-of-hospital births attended by a midwife. In this case there appears to be a potential inverse relationship with urbanization.

The greatest change in midwife-attended births over the years from 1975 to 1988 was concentrated, not surprisingly, in those states where hospital-based midwife activity was dominant (Figure 4). The 15 states that experienced at least a 4-percentage-point increase are located at the four corners of the continental United States; some (Florida, Connecticut, Minnesota, Alaska, and California) clearly show a change based on the increase in midwife-attended hospital births, whereas others (Vermont, Oregon) have a more mixed pattern. Four of the five states that experienced a decrease were in the South, and the decline was concentrated among Black mothers.

The analysis suggested a number of variables that might influence the frequency of midwife-attended deliveries in a state (e.g., population density, wealth, race) and there are several variables of interest (e.g., neonatal and infant mortality rates) that might in turn be related to midwife activity. An analysis of the Pearson product-moment correlations between a range of relevant variables and midwife-attended births in the states uncovered few statistically significant relationships. Of interest is the lack of a stronger relationship between midwife activity in 1975 and in 1988, with a correlation of only .32 between the proportions of all births in a state attended by midwives. Therefore, not only was there growth in the number of midwife-attended births, but there was a changing pattern in terms of the states where midwifery was popular.

Changes in Midwifery Practice, 1975–1988

Perhaps the most noteworthy change in midwifery practice in the period studied was in the racial composition of the mothers served by midwives in 1988. Although births to non-White mothers as a proportion of all births increased from 1975 to 1988, the proportion of non-White mothers served by midwives decreased dramatically, particularly in the out-of-hospital population (Figure 5). The pattern among those non-white mothers who are Black is the same, but with an even more precipitous decline.

Differences can also be seen between Taffel's[9] analysis of data for 1978 and 1979 and the 1988 data on some of the demographic variables discussed above. Maternal characteristics, such as parity, marital status, and prenatal care, show little change over the decade. Age differences between the populations served by midwives and mothers in general were more pronounced in 1988 than in 1978–1979. Although the proportion of mothers giving birth after the age of 30 rose in general over the decade (from 19% to 29%), the growth was even greater among midwife-attended mothers giving birth outside of

hospitals (from 23% to 40%). The reverse occurred in the case of nativity. An increase in the proportion of foreign-born mothers in general (from 10% to 14%) and a decrease in the proportion of midwife-attended mothers delivering out of hospital who were foreign-born (from 29% to 25%) resulted in differences in nativity being considerably lessened. Although the overall incidence of low birthweight did not change over the decade, the proportion of low-birthweight infants born to mothers who were attended by midwives in hospitals decreased from 4.9% in 1978–1979 to 3.4% in 1988; for mothers attended by midwives outside of hospitals, the proportion decreased from 3.8% in 1978–1979 to 2.0% in 1988. This decrease in low-birthweight babies born to mothers attended by midwives is partly the result of the decrease in the number of Black mothers served by midwives. Overall, the changes in midwifery practice between 1978–1979 and 1988 appear to have further distinguished out-of-hospital births from those in hospitals: out-of-hospital midwife-attended births seem concentrated among older White mothers.

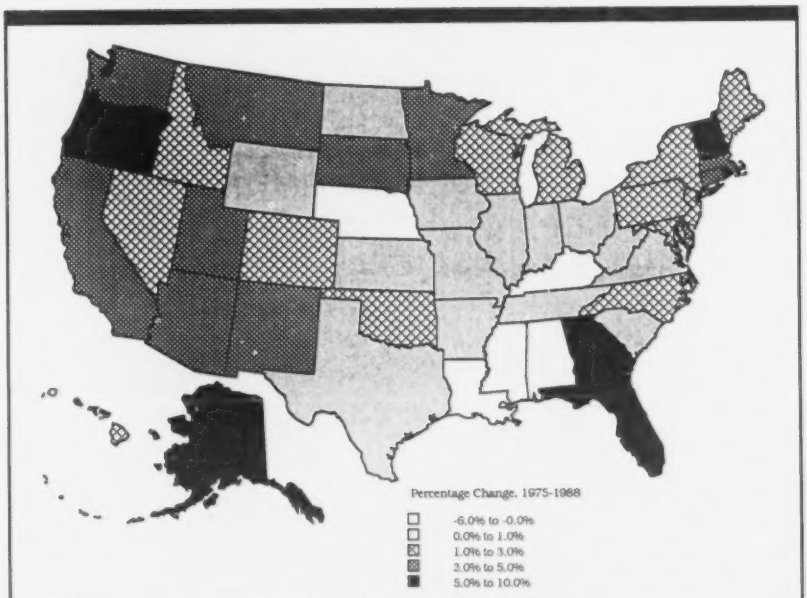

FIGURE 4—Change in midwife-attended births, 1975–1988.

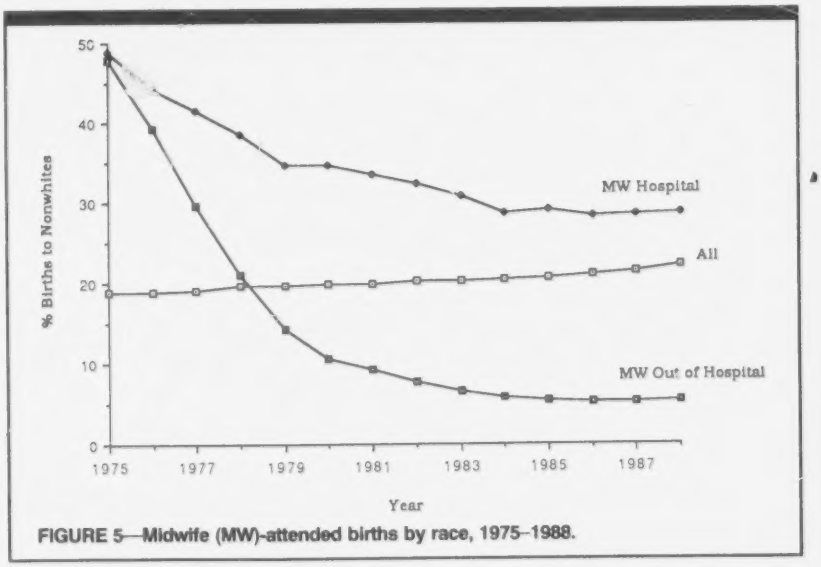

FIGURE 5—Midwife (MW)-attended births by race, 1975–1988.

Discussion

How can contemporary midwifery practice be summarized? Midwifery practice in the United States is currently hospital based: 87.3% of all midwife-attended births occurred in a hospital in 1988. Midwives who practice in hospitals serve mothers who are younger; who are more likely to be unmarried, more likely to be foreign-born, and more likely to be minorities; and who receive less prenatal care than the average mother in the United States. Midwives who attend mothers outside of hospitals support a clientele that is older, has higher parity, and is much more likely to be White; is more likely to be foreign-born and married; and receives less prenatal care than mothers as a whole. Judged by the only two measures of outcome available on birth certificates, birthweight and Apgar score, mothers and babies have distinctly better than average outcomes when births are attended by midwives, either in or out of hospitals. Despite the obvious limitations of birthweight and Apgar scores as measures of outcome, when one considers that midwives, particularly in hospitals, are serving a population apparently at risk, something about the system of care developed in these cases (careful screening of risk with referral of high risk cases to doctors, more attention to prenatal care, less intervention at birth?) is working.

The findings of positive outcomes to midwifery care are hardly unique to this study, and recent research on birth centers[14] provides more support for the increased use of midwives and suggests the need for systematic studies of the cost savings associated with midwifery care. The degree to which some of the different patterns noted above are a result of funding mechanisms (e.g., Medicaid reimbursement rules) also deserves further inquiry. Midwives can help relieve problems of access for poor and minority mothers, and midwifery care in hospitals is increasingly serving these populations. Pressures to concentrate midwifery care in these settings will likely grow and result in a clear split in midwifery practices between midwives serving the poorest mothers in hospitals and those serving upper-middle-class mothers outside of hospitals.

I found a strong regional pattern of midwife attendance at birth, and distinct interstate differences both at present and in developments over time. Because midwifery is regulated at the state level, differences are likely to persist, permitting the systematic study of the impact of both ex-

isting policies and innovative approaches to the further integration of midwifery into perinatal care in the United States. □

In Table 2, the 95% Confidence Intervals of Difference for Attitudes and Intentions were misaligned. The corrected table is printed here:

TABLE 2—Adjusted[a] 3-Month Follow-up Means by Experimental Condition

Variable	AIDS Prevention Condition	Control Condition	Difference	95% CI of Difference
Knowledge	47.20 (83)	44.40 (67)	.28	.72, 4.88
Attitudes	3.13 (82)	3.38 (67)	−.25	−.54, .04
Intentions	2.87 (82)	3.30 (67)	−.43	−.74, −.12
Risky behavior	−.12 (76)	.24 (62)	−.36	−.64, −.08

Note. Numbers of respondents are shown in parentheses. CI = confidence interval. Higher numbers indicate greater AIDS knowledge, more positive attitudes toward behaviors that increase risk of sexually transmitted HIV infection, stronger intentions to engage in such risky behaviors, and more reports of risky sexual behavior.
[a]For each variable, the preintervention measure is partialled out of the 3-month follow-up measure.

The Influence of Social and Political Violence on the Risk of Pregnancy Complications

B. Cecilia Zapata, DrPH, Annabella Rebolledo, PhD, Eduardo Atalah, MD, Beth Newman, PhD, and Mary-Claire King, PhD

ABSTRACT

Background. Events in Chile provided an opportunity to evaluate health effects associated with exposure to high levels of social and political violence.

Methods. Neighborhoods in Santiago, Chile, were mapped for occurrences of sociopolitical violence during 1985–86, such as bomb threats, military presence, undercover surveillance, and political demonstrations. Six health centers providing prenatal care were then chosen at random: three from "high-violence" and three from "low-violence" neigborhoods. The 161 healthy, pregnant women due to deliver between August 1 and September 7, 1986, who attended these health centers were interviewed twice about their living conditions. Pregnancy complications and labor/delivery information were subsequently obtained from clinic and hospital records.

Results. Women living in the high-violence neighborhoods were significantly more likely to experience pregnancy complications than women living in lower violence neighborhoods (OR=5.0; 95% CI=1.9–12.6; p<0.01). Residence in a high-violence neighborhood was the strongest risk factor observed; results persisted after controlling for several sets of potential confounders.

Conclusion. Living in areas of high social and political violence increased the risk of pregnancy complications among otherwise healthy women. (*Am J Public Health.* 1992; 82:685–690)

Introduction

Research on the health effects of social and political violence has typically focused on individuals victimized by violent acts[1–8] and neglected the population at large, which in a troubled time or place is often exposed to a pervasive atmosphere of fear and tension. The influence of such an atmosphere on health is now being investigated more frequently.[9,10] The recent political unrest in Chile provided an opportunity to assess the impact of social and political violence on the risk of pregnancy complications in otherwise healthy women.

Between 1973, when President Salvador Allende was overthrown by a military coup d'état, and 1990, Chile experienced widespread social and political upheaval. The commanders-in-chief of the Army, Navy, Air Force, and National Police created a military junta, headed by General Augusto Pinochet Ugarte. The junta adjourned the National Congress, dismissed elected officials, closed the constitutional court, and banned activities of political parties and labor unions. Extrajudicial killings, disappearances, forcible exiles, and arbitrary arrests reached unprecedented levels.[11,12] The government rationalized its activities by decreeing a "state of exception" in 1973, which permitted new legislation restricting basic human rights.[11] Under this decree, the military junta declared the country variously under state of siege, state of emergency, and state of alert.

During the period of this study, from December 1985 to December 1986, Chile was continually under a state of exception or state of emergency (December 1985 to August 1986) or under a state of siege (September to December 1986). The atmosphere in Chile, especially in greater Santiago, was one of confrontation between civilians and the police and armed forces. During this period, there were 33 665 political arrests.[13,14] An especially active period was April 29 to May 13, 1986, when joint military and police forces raided 33 neighborhoods in greater Santiago and southern Chile. Despite the government's prohibition of strikes, Chileans went on a nationwide general strike on July 2 and 3, 1986. The government declared the strike illegal and hundreds of people were arrested. In Santiago 2 people were burned alive by the military (one died, the other survived),[14] 4 opponents of the government were kidnapped and executed, and at least 132 cases of torture were openly denounced in the courts. The staff of the Human Rights Commission suffered 32 arrests, 2 kidnappings, 86 threats, and 13 cases of cruel, inhumane, or degrading treatment.[13] The Vicariate of Solidarity of the Catholic Church had 5 of its staff arrested, received 17 threats, and experienced 1 unsuccessful assassination attempt.[13] A physician and a lawyer employed by the Vicariate, as well as a private physician, faced charges of terrorism

At the time of this study, B. Cecilia Zapata, Beth Newman, and Mary-Claire King were with the School of Public Health, University of California, Berkeley. B. FIGURE 1—Location of six health centers in Santiago, Chile, according to levels of sociopolitical violence.

because they assisted a wounded man who sought medical assistance in a clinic under contract with the Vicariate of Solidarity.[13]

However, social and political violence, unrest, and crime were not distributed equally throughout Chile in general, or across Santiago in particular. Our goal was to study prospectively pregnancy complications among healthy Chilean women who received prenatal care at the health centers but who lived under different levels of social and political violence.

Methods

For the purpose of this study, a team of researchers from the School of Medicine of the Universidad de Chile mapped Santiago according to the frequency of occurrence of five classes of events: police and military presence, undercover police activity, bomb threats, demonstrations, and lack of reliable public transportation before the curfew hour. Neighborhoods were classified as having high or low levels of sociopolitical violence (Figure 1). From among Santiago's 58 health centers, we randomly selected 3 from high-violence areas and 3 from low-violence areas. The director of each of these six health centers was then asked to independently rate the level of sociopolitical violence in the neighborhood of his health center. The directors' assessments were generally in agreement with our mapping designations. However, some of the directors pointed out small areas that were within generally low-violence neighborhoods, but because of special circumstances were actually at high risk of sociopolitical violence (e.g., a block containing the heavily guarded home of a member of the military junta). The 22 women who lived in such pockets were reclassified from the low-violence to the high-violence category to reflect actual exposure. Assignments to exposure were made prior to any data collection.

Our study sample comprised pregnant women between 19 and 40 years of age who were enrolled for prenatal care at the six selected health centers, lived within the clinics' target areas, had no chronic medical conditions, and (based on the date of the last menstrual period) were due to deliver between August 1 and September 7, 1986. The sample consisted of 179 women, 113 living in areas with high levels of sociopolitical violence and 66 living in areas of lower sociopolitical violence.

The first interview with each woman was conducted between March 13 and April 13, 1986, by professional interviewers from the Universidad de Chile and one of the authors (B.C.Z.). The interviews took place in the subjects' homes. The second interviews took place from June 18 through July 7, 1986. These dates correspond to the end of the first trimester or the beginning of the second trimester of pregnancy for the first interview and to the third trimester for the second interview. Between the times of the first and second interviews, 13 respondents moved out of the target area, 4 had late miscarriages, and 1 refused to continue to participate for lack of time. The final sample was therefore composed of 161 women, 106 from areas of high sociopolitical violence and 55 from areas of low sociopolitical violence. The 18 women lost to the second interview did not differ from the final cohort with respect to age, marital status, or prenatal care.

The interviews addressed potential influences on pregnancy, including length of residence in the neighborhood, the respondent's positive and negative relationships with her neighbors, family composition and relationships between the respondent and members of the household, strains within the family, violence in the home, employment and personal economic status, smoking and alcohol consumption, nutrition, health-related issues, and educational level. A series of questions allowed the construction of scales measuring social support,[15] life events,[16] alienation,[17] depression,[15,16,18,19] locus of control (helplessness),[15–17] and neighborhood satisfaction. All scales were coded so that a higher score represented a potentially negative attribute, for example, more negative life events or less social support. We also asked the women a series of questions about their perceptions of sociopolitical violence in their neighborhoods (neighborhood milieu) at interviews 1 and 2.[20]

All women received prenatal and delivery care from professional midwives. If a woman developed a health problem that might influence her pregnancy or delivery, she was referred to an obstetrician. All diagnoses of pregnancy and delivery complications were made by this team of health care providers after appropriate clinical and laboratory tests and were documented in the medical records. Medical

records were reviewed at the health centers after the second interview was completed, and hospital records were reviewed after delivery. All medical records were abstracted according to a structured abstracting form by three health professionals from the School of Medicine of the Universidad de Chile who did not know exposure status. Complications of pregnancy were defined as any of the following clinical diagnoses: gestational hypertension; pre-eclampsia, eclampsia, or toxemia; bleeding at first, second, or third trimester; threat of miscarriage; threat of premature labor; premature rupture of membranes; late miscarriage (stillbirth); painful preterm contractions requiring bed rest and sexual abstinence or hospitalization; and fetal growth retardation. A woman was considered subject to pregnancy complications if she had any two or more of these complications or one extremely severe complication. In the latter category were three women, two who developed eclampsia and one who gave birth to a stillborn fetus.

Odds ratios (ORs) and confidence intervals (CIs), as well as chi-square and *t* test statistics, were used to test associations of possible risk factors and pregnancy complications. Risk factors associated with pregnancy complications were also entered into logistic regression models to adjust for confounding effects. SAS data management and analysis programs were used throughout.[21–23]

Results

All 161 women had prenatal care throughout their pregnancies. The women who fell below expected weight gain during pregnancy (19%) were assigned by the health care provider to a supplementary food program through the health center. Pregnancy complications by health center are indicated in Table 1. Forty-six women had two or more complications; 115 women had one or zero complications. These two groups did not differ (at $P < .20$) in most demographic and health-related characteristics (Table 2). Age was associated with increased risk of pregnancy complications ($\chi^2 = 6.49$, $df = 3$, $P = .09$): women younger than 25 years of age and women older than 34 years of age were at greater risk of two or more pregnancy complications.

Among psychosocial indicators, risk of pregnancy complications was marginally associated with higher levels of alienation ($P = .13$) and lower levels of social support ($P = .18$) (Table 3). Other psy-

TABLE 5—Independent Predictors of Pregnancy Complications among Women in Santiago, Chile, 1986: Final Multiple Logistic Regression Model

Risk Factor	Odds Ratio	95% Confidence Interval	*P* Value
Sociopolitical violence (high vs low, defined by mapping)	5.0	1.83, 12.77	<.01
Social support[a]	1.9	0.92, 4.07	.08
Neighborhood milieu at interview 1	1.9	0.78, 4.86	.15

[a]Scales were dichotomized, and odds ratios compare women scoring above the median to women scoring below the median (reference group).

chosocial indicators were not associated with risk of complications.

The fundamental question addressed in this study was whether living in a neighborhood of high sociopolitical violence was associated with pregnancy complications. Of the 55 women living in areas of low sociopolitical violence, 6 (11%) had at least two pregnancy complications, whereas among the 106 women living in areas of high sociopolitical violence, 40 (38%) had at least two pregnancy complications (Table 4). Thus women living in high-violence neighborhoods, as defined a priori, were at significantly increased risk of pregnancy complications (OR = 5.0, 95% CI = 1.9, 12.6). The woman's own perception of her neighborhood milieu was also associated with an increase in risk (OR = 1.8, 95% CI = 0.8, 4.3 at interview 1 and OR = 1.8, 95% CI = 0.9, 3.6 at interview 2). The presence of violence in the home was not significantly associated with an increased risk of pregnancy complications (OR = 1.5, 95% CI = 0.8, 3.2).

Multiple logistic regression was used to assess the independent effects of age, low social support, high level of alienation, perception of neighborhood milieu, and sociopolitical violence in the neighborhood, that is, all variables for which $P < .20$ in previous analyses. Because several of the variables were not independently associated with the risk of pregnancy complications in the multivariate analysis, a second model included only the three variables that remained predictive of pregnancy complications at $P < .20$ (Table 5). A fivefold increase in the risk of pregnancy complications was associated with living in high-violence versus low-violence neighborhoods, after adjustments were made for lack of social support and perception of neighborhood milieu at interview 1.

Several variables were associated with living in high-violence neighborhoods, including income, education, marital status, underweight, cigarette smoking, dissatisfaction with neighborhood, life events (at interview 2), neighborhood milieu (at interview 1), alienation, uncertainty, and depression (at interview 1). Most of these variables were not directly associated with pregnancy complications. However, we chose to include them in a multiple logistic model as potential confounders of the association between living in a high-violence neighborhood and risk of pregnancy complications. The results of this multivariate analysis closely paralleled those shown in Table 5. The only predictive variables were sociopolitical violence of the neighborhood (OR = 5.3, $P < .01$), alienation (OR = 1.8, $P = .18$), and neighborhood milieu at interview 1 (OR = 1.9, $P = .17$). The *P* values for all other variables in the model were higher than .4.

To assess whether the apparent effect of neighborhood sociopolitical violence resulted from differences in diagnosis of pregnancy complications among the health centers, we tested for an association between specific health center and risk of pregnancy complications separately for high-violence neighborhoods and low-violence neighborhoods. The fact that no significant associations were ob-

served suggested that the levels of violence in the health centers' neighborhoods, rather than characteristics of the health centers themselves, influenced pregnancy complications. However, we did find an interaction between neighborhood violence and social support in these analyses. Within high-violence neighborhoods, lower levels of social support were significantly associated with risk of pregnancy complications (OR = 3.1, 95% CI = 1.3, 7.6). In other words, women exposed to high levels of violence in their neighborhoods who also had less social support were more likely to have pregnancy complications than were women in the high-violence neighborhoods whose social support was stronger.

Discussion

The purpose of this study was to determine whether there was a difference in pregnancy complications between women who live under high levels of sociopolitical violence and women who live under less violent conditions. After adjusting for potential confounders, we found that high levels of sociopolitical violence were associated with an approximately fivefold increase in risk of pregnancy complications. Two subjective measures, lack of social support and perceived sociopolitical violence (neighborhood milieu), also independently contributed approximately twofold increases in risk of pregnancy complications among otherwise healthy women. The latter results are similar to those found in other studies of pregnancy complications.[24–26]

One potential source of bias in this study is possible misclassification of women's exposure to violence. However, the use of objective indicators of sociopolitical violence to categorize neighborhoods, as well as the independent confirmation by the health centers' directors, gives us confidence in our mapping efforts. Moreover, the ability of the health centers' directors to identify pockets of high sociopolitical violence within areas classified as low-violence gave us the opportunity to identify more precisely the level of violence within neighborhoods and to assign women appropriately.

The prospective nature of the study precluded the possibility of assigning exposure status on the basis of outcome. Pregnancy complication information was obtained after completion of both interviews by medical record abstractors who were unaware of whether a woman resided in a high- or low-violence neighborhood. Moreover, the medical care providers did not know which pregnant women were included in our study. Nevertheless, we addressed the possibility that medical care or diagnostic practices may have differed by health center and thereby influenced our findings. The fact that these analyses revealed no association between health centers and pregnancy complications after we controlled for level of sociopolitical violence suggests that differential ascertainment of pregnancy complications was not a problem.

We were initially concerned about the respondents' willingness to participate fully in our prospective study. However, our response rate was 100% of those contacted and eligible at the first interview and 99% of those still living in the target areas and still pregnant at the second interview. The sample was relatively small, but it was representative of healthy pregnant women in Santiago who received prenatal care at the health centers. This group includes the majority of lower-middle-class, working class, and unemployed pregnant women in Santiago. Our conclusions cannot be generalized to pregnant teenagers, women with chronic illness, or those not receiving prenatal care.

Public Health Implications

Violence is a public health issue and deserves the attention accorded to any other cause of morbidity and mortality in human populations. Some countries have a specialization called trauma medicine, which deals with severe body damage caused by violence. New techniques in psychiatry and psychology have contributed to the healing of invisible wounds left by political violence. Two of the best examples of efforts to address violence are the centers for the rehabilitation of victims of torture in Denmark[27] and Los Angeles.[7]

Medical resources for curing or rehabilitating victims of violence are scarce, but preventive measures in the medical and public health disciplines are nonexistent. Most of the work on the prevention of violence in general, and political violence in particular, is being done by nonprofit groups and organizations. It is not too late for the public health field to effectively address its negligence of social and political violence and the threat such violence represents to the lives of individuals and communities.

To our knowledge, this is the first study of the effect of sociopolitical violence on pregnancy complications. Four women in our study miscarried after 20 weeks' gestation. All four resided in high-violence areas. Among the other women, complications were generally mild or moderate. The finding that healthy women were more subject to pregnancy complications if they lived in high-violence neighborhoods thus reflects unexpected health consequences of sociopolitical violence in a vulnerable population. The fact that 98% of these women carried their pregnancies to term despite the reality of violence in their neighborhoods during their pregnancies is a tribute, in our view, to their ability to cope and to the excellent care provided by their neighborhood health centers.

Research on health-related effects of social and political violence is very limited, particularly in communities that experience high levels of violence for prolonged periods of time. Clearly, this study requires confirmation with a larger sample and other populations. At the same time, data are needed on the long-term effects of sociopolitical violence on the postpartum and neonatal well-being of mothers and their infants, as well as on other sectors of the general population. As public health professionals, we can contribute to the control of social and political violence by actively engaging in the study and prevention of such violence. □

Acknowledgments

This study was supported by a Fulbright Foundation grant to (Dr Zapata, 1985–1986) and by the Grossman Fund of the University of California, Berkeley, School of Public Health. This research was approved by the Chilean Ministry of Health on February 18, 1986.

The results of this study were presented at the 117th Annual Meeting of the American Public Health Association, October 1989, in Chicago. Sources of Fiber and Fat in Diets of US Women Aged 19 to 50: Implications for Nutrition Education and Policy

ABSTRACT

Introduction. Many women are not meeting dietary recommendations for fiber and fat intakes. Health educators need to know which foods are major sources of these nutrients.

Methods. This study analyzed the contributions of 27 food groups to fiber, fat, saturated fat, and cholesterol intakes of 2134 women aged 19 to 50 years in USDA's Continuing Survey of Food Intakes by Individuals, the 1985 and 1986 surveys (CSFII 85–86).

Results. Major determinants of fiber intake include frequency of use of certain food groups (vegetables, including potatoes, bread, fruit, soups, ready-to-eat cereal) and choice of particular foods within the larger food groups (e.g., whole grain bread, high fiber cereal). Major determinants of total fat, saturated fat, and cholesterol intakes included frequency of use of certain foods (sweet grains, beef, eggs, cheeses/cream, whole milks) and additions to foods (regular salad dressing and butter/margarine). Demographic characteristics were related to various food group consumption parameters.

Conclusions. Information about the relationships between food group and nutrient intake and the effects of household income, race/ethnicity, and region of residence on food group intake indicate opportunities to refine nutritional education programs. (*Am J Public Health*. 1992;82:695–702)

Introduction

According to the Joint Nutrition Monitoring Evaluation Committee, the federal advisory committee jointly established by the US Departments of Agriculture (USDA) and Health and Human Services (HHS) to monitor the nutritional status of the US population, the principal nutrition-related health problems in the United States today arise from overconsumption of fat, saturated fatty acids, cholesterol, and sodium.[1] Epidemiological and clinical studies suggest that diets high in plant foods are associated with lower risk of coronary heart disease, colon cancer, diabetes mellitus, diverticulosis, hypertension, and gallstone formation.[2] In response to growing evidence concerning the relationships between diet and chronic diseases, a number of private and public organizations,[3–9] most recently USDA and HHS in their 1990 *Dietary Guidelines for Americans*,[10] have made specific quantitative recommendations about how much fiber and fat Americans should be consuming for optimal health.

Comparison of individual food consumption data collected by USDA in the 1977–78 Nationwide Food Consumption Survey (NFCS) and the 1985 Continuing Survey of Food Intakes by Individuals (CSFII 85) indicates that fat intake may have been decreasing in recent years. The mean intake of total fat for women 19 to 50 decreased from about 73.9 g per day[11] (40.8% of kilocalories from fat[2]) in 1977–78 to 63.1 g per day (36.8% of kilocalories from fat) in 1985.[12] Fiber intake was not estimated in the 1977–78 NFCS. The mean fiber intake for women 19 to 50, estimated from CSFII 85, was 10.6 g per day.[12]

Many women are not meeting dietary recommendations for fiber and fats. In order to provide effective advice to women on how to increase fiber and reduce fat intakes, health educators and nutritionists need to know which foods are major sources of these nutrients among various subgroups of women, defined by important demographic characteristics, and which eating practices account for differences in fiber and fat intakes. In this paper we address these questions.

Methods

Sampling and Study Procedures

Data from the USDA's Continuing Survey of Food Intakes by Individuals 1985 and 1986 (CSFII 85-86) core sample surveys were used. The design of these surveys provided two multistage stratified area probability samples of women aged 19 through 50 and their children aged 1 through 5, representative of the 48 conterminous states.

In order to ensure comparability of the CSFII 85 and the CSFII 86, the same area segments were sampled in the two surveys. However, different housing units were selected for each survey. The data collection and data processing procedures used in the two surveys were identical.

Survey participants were asked to provide six nonconsecutive 1-day dietary

The work was performed at the Division of Nutritional Sciences, Cornell University, Ithaca, NY.

This paper was submitted to the Journal December 27, 1990, and accepted with revisions October 18, 1991.

TABLE 1—Description of 27 Food Groups Analyzed

Food Group	Foods Included
Beef	Beef, veal, lamb, and goat, solid and ground, except that contained in mixtures
Poultry	All poultry: chicken, turkey, and game birds, except that contained in mixtures
Fresh pork	Fresh (not cured) pork, except that contained in mixtures
Lunch meats, bacon	Franks, sausages, lunch meats, potted meat or spreads (including sandwiches), bacon, salt pork
Fish	All fish: finfish and seafood, except that contained in mixtures
Cured meat, organ meat, miscellaneous meat	Cured, smoked, pickled meat, game, organ meat, miscellaneous meats, and meat parts
Meat, fish, poultry mixtures	Beef, lamb, veal, goat mixtures, frozen plate meals, beef and veal sandwiches, pork mixtures, poultry mixtures, fish mixtures
Nuts, seeds	All nuts and seeds, nut butters
Eggs	Eggs and egg mixtures such as egg salad, omelettes
Whole milks	Whole milk, fluid and dry, flavored and plain; evaporated milk
Low-fat milks, cottage cheese, yogurt	Low-fat and skim milk, fluid and dry, low-calorie flavored milk drinks, yogurt, cottage cheese and other low-fat cheeses
Cheeses/cream	Natural cheese, processed cheese, cream cheese, cream and cream substitutes
Dairy/frozen desserts	Gelatin desserts, ices, popsicles, sherbert, puddings, ice cream
Soups/dried beans	All soups, including vegetable, meat, poultry, fish, and bean soups; dried beans
Mostly grain/vegetable mixtures	Mixtures with pasta or rice, pizza, Hispanic mixed dishes, Asian mixed dishes
Rice/pasta	Rice, pasta
Bread	Yeast breads, white and whole grain
Biscuit/cornbread/cooked cereals	Biscuits, grits, cornmeal mush, cornbread, cooked cereals
Ready-to-eat cereals	All ready-to-eat breakfast cereals
Fruits	All fruits, including dried fruits
Fruit juices	All fruit juices, nectars, tomato juice
White potatoes	White potatoes, prepared all ways
Vegetables, not white potatoes	All vegetables other than white potatoes and other than olives, pickles, relishes, and pickled vegetables
Sweet grain products	Sweet rolls, pancakes, pies, eclairs, cakes, cookies, sweet crackers
Salty snacks	Crackers and salty snacks, including popcorn and pretzels, potato chips/sticks
Butter/margarine	Butter, margarine
Regular salad dressing	Mayonnaise, all regular salad dressings

recalls collected at approximately 2-month intervals throughout a year. Interviews occurred from April 1985 through March 1987. Eligible households were scheduled for interviews on different days of the week to provide representativeness of dietary intake data over all days of the week. The first interview was conducted in person; subsequent interviews were conducted by telephone for 91% of the sample. Standard methods were used for conducting the interview.[12,13]

While the design of the survey called for collection of 6 nonconsecutive days of information, less than half of the CSFII 85-86 respondents interviewed initially completed the full 6 days of report. Consequently, USDA constructed a sample of all women who had completed any 4 of the possible 6 days of report, 71% of the initial CSFII 85 sample and 76% of the initial CSFII 86 sample. For all selected women, the first day of information was included. For those women who reported 5 or 6 days of information, USDA randomly selected the 3 additional days included. The combined CSFII 85-86 data set used in these analyses includes 2134 women, each with 4 days of dietary information. A more complete description of the sampling and study procedures is found in CSFII reports 85-4[12] and 86-3.[13]

Variable Definition

All individual foods reported were classified into 89 food groups based on patterns of use, frequency of use, and nutrient composition. Foods that were eaten together and reported as one food item, rather than reported as separate component foods, were categorized into mixture food groups (e.g., beef sandwiches). For each respondent, the total amount of the food group consumed in grams, the total frequency of food group use, and the amount of nutrient (e.g., fat) consumed from the food group were calculated for each food group. The 89 food groups were also aggregated into a system of 33 food groups. Most of these analyses used the system of 33 food groups, although some used the system of 89 food groups when a greater level of detail was required. Six of the 33 food groups contained no fat or fiber, and so were omitted from these analyses. The 27 food groups remaining are described in Table 1.

In order to examine the effects of specific eating practices on overall nutrient intake, the frequency of consuming each food group (measured as the number of times foods from the food group were consumed over the 4 days of report), the serving size (in grams) of the food group when it was consumed, and the nutrient density of the food group when it was consumed (e.g., the amount of fat present in a 100-g serving of that food group) were specified. The density measure reflects the fact that a different mix of foods with a different average nutrient composition might have been consumed by different individuals. For example, an individual who chose relatively high-fat hamburger would have a higher fat density in the ground beef food group than would an individual who chose lower fat hamburger.

Analytical Methods

In order to determine the major food group sources of fiber, fat, saturated fatty acids, and cholesterol in the population's diet, the mean amount of nutrient contributed by each food group to the population's total nutrient intake was estimated by averaging the nutrient from food group variable over all individuals. The mean proportion each food group contributed to nutrient intake was estimated as follows: The total amount of nutrient consumed from each food group was summed over all individuals. This was divided by the total amount of nutrient consumed from all food groups summed over all individuals. This analysis was performed on the total sample and on subgroups of the sample stratified by household income as a percentage of poverty ($\leq$185% vs $>$ 185%), ethnicity (White, Black, Hispanic; others omitted because of small numbers),

and region of residence (Northeast, Midwest, South, and West).

In order to compare specific eating practices of women at different levels of nutrient intake, the sample was divided into quartiles based on that nutrient intake. Mean levels of eating practice variables between women in the first quartile and women in the fourth quartile were compared.

Weighting factors that adjust for household and individual nonresponse were provided by USDA and incorporated in all analyses. Weighted proportions, quartile levels, and means adjusting for nonresponse were estimated using SAS.

Results

Intakes of Fiber and Fats for Demographic Subgroups

Mean daily intakes of fiber and fats for women aged 19 to 50 are shown in Table 2. White women have higher fat and saturated fatty acid intakes but lower cholesterol intakes and higher fiber intakes. Household income as a percentage of poverty is directly associated with fat, saturated fatty acids, and cholesterol intakes. Women in the Northeast have the lowest intakes of fat, saturated fatty acids, and fiber. Women in the Midwest and West have greater intakes of fiber and saturated fatty acids.

While the diets of many women are in accordance with the cholesterol recommendation, the diets of most women contain lower than recommended amounts of fiber and higher than recommended amounts of total fat and saturated fatty acids (Table 3). More Hispanics are meeting recommendations for fat and saturated fatty acids. Fewer Whites meet the saturated fatty acid recommendation, and fewer Blacks meet the cholesterol recommendation. Higher household income as a percentage of poverty is associated with lower prevalences of meeting the percentage of kilocalories from fat and saturated fatty acids recommendations and is unrelated to the prevalence of meeting the cholesterol recommendation.

TABLE 2—Weighted Mean Daily Nutrient Intake of Women 19–50 by Demographic Characteristics: CSFII 85-86

Demographic Characteristics	n	Fat, g	Kilocalories from Fat, %	Saturated Fat, g	Kilocalories from Saturated Fat, %	Cholesterol, mg	Fiber, g

Fiber

Food group sources by poverty level. The food group vegetables other than potatoes contributes nearly a quarter of the total amount of fiber consumed in both lower and higher income women (Table 4). (Note that this does not include vegetables eaten in meat and grain mixtures or soups.) Fruits and ready-to-eat cereals are more important contributors to fiber intake among higher income women; white potatoes and soups/dried beans are more important contributors among lower income women.

Eating practices. Diets in the fourth (highest) quartile of fiber consumption average about 17.5 g of fiber daily; those in the first (lowest) quartile average about 5.4 g daily. Although women in the fourth quartile of fiber consumption generally consume the major fiber food groups with greater frequency, serving size, and fiber density than do women in the first quartile, the largest differences are in the frequency of eating component (data not shown). The mean frequency of use for six of the eight food groups examined (i.e., vegetables other than potatoes, bread, fruits, white potatoes, soups/dried beans, and ready-to-eat cereals but not grain mixtures and meat/fish/poultry mixtures) is substantially higher among women in the

TABLE 4—Weighted Food Group Sources of Fiber Intake among Women 19–50 by Household Income: CSFII 85-86

Household Income/Food Group	Fiber, g/day	% of Total	Household Income/Food Group	Fiber, g/day	% of Total
≤185% of poverty (n = 726)[a]			>185% of poverty (n = 1408)[b]		
Vegetables other than white potatoes	2.3	23.5	Vegetables other than white potatoes	2.8	24.4
Bread	1.2	12.5	Bread	1.5	13.3
White potatoes	1.1	11.1	Fruits	1.4	12.2
Soups	0.9	9.3	White potatoes	1.0	8.6
Fruits	0.8	8.3	Mostly grain, vegetable mixtures	0.7	6.6
Mostly grain, vegetable mixtures	0.7	7.2	Ready-to-eat cereals	0.6	5.7
Meat, fish, poultry mixtures	0.6	6.2	Meat, fish, poultry mixtures	0.6	5.2
Sweet grain products	0.4	3.9	Soups	0.6	5.1

Note. CSFII 85-86 = Continuing Survey of Food Intakes by Individuals 1985 and 1986.
[a]Weighted mean daily fiber intake is 9.7 g.
[b]Weighted mean daily fiber intake is 11.3 g.

fourth vs first fiber quartile. The mean serving size is somewhat greater for white potatoes, vegetables other than white potatoes, ready-to-eat cereals, grain mixtures, and meat/fish/poultry mixtures. The mean fiber density is substantially greater for ready-to-eat cereals and bread but not for the other six food groups examined.

We also examined the contribution of raw vegetables (mainly salads) to fiber differences between the two quartiles of women. Those in the highest vs lowest fiber quartile consume raw vegetables more frequently (2.7 vs 1.5 times over 4 days). Mean serving size and fiber density are similar.

Food patterns. In order to increase fiber, the USDA–HHS dietary guidelines,[10] the National Cancer Institute (NCI),[8] and the National Academy of Sciences[2] recommend that adults eat daily at least five servings of vegetables and fruits and six servings of grain products, several of which should be whole grain. Although women obtain fiber from these food groups, their frequency of consumption of these foods is much lower than advised. We estimate that among women 19 to 50, the average daily number of servings of vegetables (including legumes) is 2.6; of fruits or fruit juices, 0.8; and of grain products, 2.8 (Table 5). Only 10% eat a cereal that contains at least 5 g of fiber per serving at least once over 4 days. Furthermore, while 47% eat whole grain bread at least once over 4 days, only 26% of all bread consumed is whole grain.

The number of servings of vegetables, fruits, and grains consumed increases with increasing household income (Table 5), although consumption of potatoes and dried beans/soups is similar across three income groups. Whites consume the greatest number of servings of vegetables, fruits, and grains, followed by Hispanics and Blacks. Women in the West have the highest number of servings of total vegetables, total fruits/juices, and whole grain bread.

Total Fat

Food group sources by poverty level. Since fat is widely dispersed in our foods, nearly all of the 27 food groups contribute some fat to the population's total fat intake. Grain mixtures, meat/fish/poultry mixtures, beef, sweet grains, cheeses/cream, and butter/margarine are major sources of fat for both income groups (Table 6). However, lunch meats/bacon and whole milks are more important food group sources among lower income women, while regular salad dressing is more important among higher income women.

[a]Weighted mean daily fat intake is 58.6 g.
[b]Weighted mean daily fat intake is 63.5 g.

Food group sources by region and race/ethnicity. Grain mixtures and beef are important sources of fat among all race/ethnicity groups (Table 7). Salad dressing is more important among Whites and among women in the West and Northeast; franks/bacon is more important among Blacks and among women in the Midwest and South; poultry is more important and meat mixtures and sweet grains are less important among Blacks; and grain mixtures are more important among Hispanics.

Eating practices. Dietary guidelines suggest using low-fat preparation methods, yet it appears that certain high-fat preparation methods are prevalent among women aged 19 to 50. For example, we estimate that about 71% of the time, poultry is eaten fried or breaded and/or with the skin not removed. Pork is eaten untrimmed and fried or breaded about 68% of the time.

We estimate that women in the fourth vs first quartile of fat consumption average 95.3 vs 33.6 g of fat daily, 40.4% vs 31.7% of kilocalories from fat. The mean frequency of use and the mean serving size when used are lower in women in the first vs fourth fat quartile for grain mixtures, sweet grains, regular salad dressing, lunch meats/bacon, butter/margarine, and cheeses/cream (data not shown). In addition, women in the fourth fat quartile choose foods within the food groups of meat mixtures and beef that have a somewhat greater amount of fat per 100-g serving than foods chosen by women in the first fat quartile.

Saturated Fatty Acids

Food group sources by poverty level. Fewer foods are sources of saturated fatty acids, since saturated fatty acids occur predominantly in animal foods and infrequently in plant foods. Grain mixtures, meat/fish/poultry mixtures, and sweet grains are important food group sources for all women (Table 8). Beef, whole milks, and lunch meats/bacon are more important contributors to the saturated fatty acid intake among lower income women, while cheeses/cream and butter/margarine are more important among higher income women.

Food group sources by region and race/ethnicity. Cheeses/cream, grain mixtures, and beef are important sources of saturated fatty acids among women in all regions (Table 9). Whole milks are more important among women in the Northeast and among Hispanics. Franks/bacon is more important among women in the Midwest and South and among Blacks.

Eating practices. Among women aged 19 to 50, we estimate that those in the fourth vs first quartile of saturated fatty acid consumption consume an average of

TABLE 8—Weighted Food Group Sources of Saturated Fatty Acid Intake among Women 19–50 by Household Income: CSFII 85-86

Household Income/Food Group	Saturated Fatty Acids, g/day	% of Total	Household Income/Food Group	Saturated Fatty Acids, g/day	% of Total
≤185% of poverty (n = 726)[a]			>185% of poverty (n = 1408)[b]		
Beef	2.1	9.7	Natural, processed cheeses, cream	2.7	11.6
Natural, processed cheeses, cream	2.0	9.5	Mostly grain, vegetable mixtures	1.9	8.2
Mostly grain, vegetable mixtures	1.9	8.8	Beef	1.9	8.2
Whole milks	1.6	7.6	Meat, fish, poultry mixtures	1.7	7.4
Meat, fish, poultry mixtures	1.6	7.4	Butter/margarine	1.5	6.5
Lunch meats, bacon	1.6	7.3	Sweet grain products	1.5	6.5
Sweet grain products	1.2	5.4	Lunch meats, bacon	1.3	5.7
Butter/margarine	1.1	4.9	Whole milks	1.3	5.6

Note. CSFII 85-86 = Continuing Survey of Food Intakes by Individuals 1985 and 1986.
[a]Weighted mean daily saturated fat intake is 58.6 g.
[b]Weighted mean daily saturated fat intake is 63.5 g.

35.9 vs 11.5 g of saturated fatty acids daily, 15.6% vs 10.7% of kilocalories from saturated fatty acids.

The mean frequency of use and mean serving size when used are substantially lower among women in the first vs fourth quartile of saturated fatty acid intake for cheeses/cream, grain mixtures, whole milks, lunch meats/bacon, butter/margarine, and sweet grains (data not shown). In addition, women in the fourth quartile vs first quartile are consuming butter/margarine of higher saturated fatty acid density.

Cholesterol

Food group sources by poverty level. The food group eggs contributes about a third of the cholesterol intake among women in lower and higher income groups (Table 10). Beef, meat/fish/poultry mixtures, grain mixtures, poultry, and sweet grains are also major contributors among women in both income groups. Organ, cured, miscellaneous meats and whole milks are more important contributors among lower income women. Cheeses/cream and fish are more important contributors among higher income women.

Food group sources by region and race/ethnicity. Differences in food group sources of cholesterol are less striking, since eggs constitutes the dominant food group source across all demographic subgroups (data not shown). Beef and meat mixtures are also important sources across all regions. Poultry and cured, organ, miscellaneous meats are more important among Blacks. Sweet grains is more important among women in the West.

Eating practices. Among women aged 19 to 50, we estimate that those with diets in the fourth vs first quartiles of cholesterol consumption average 472 vs 124 mg of cholesterol daily. The mean frequency of use and the mean serving size when used are lower among women in the first vs fourth quartile of cholesterol intake for eggs, beef, grain mixtures, and sweet grains (data not shown). These differences are especially substantial for eggs (0.2 vs 2.1 times in 4 days; 40- vs 87-g serving size). The cholesterol density of grain mixtures and sweet grains is higher among women in the fourth vs first cholesterol quartile.

Discussion

Major sources of fiber for women aged 19 to 50 are not only the foods in vegetables, grains, and fruits food groups eaten by themselves, but also in mixtures

[a]Weighted mean daily cholesterol intake is 280 mg.
[b]Weighted mean daily cholesterol intake is 273 mg.

(i.e., grain mixtures, soups, and meat/fish/poultry mixtures). The frequency of consumption of these food groups and the choice of particular foods within the food groups are creating large differences in fiber intake.

Women with the highest fiber intakes consume vegetables (including raw vegetables), bread, and fruits much more frequently than do those with the lowest fiber intakes. Women with higher fiber diets are also choosing higher fiber kinds of bread and ready-to-eat cereals.

However, few women are meeting the NCI recommendation of 20 g daily of fiber. In order to meet this recommendation using dietary guidance provided by USDA, and NCI[14,15] women need to increase their vegetable consumption and double their consumption of grain products and fruits.

For fats, it appears that the frequency of consumption of certain food groups, the use of certain additions to foods, and preparation methods used for these foods are responsible for the large differences in fat intake among women aged 19 to 50.

Disappearance data indicate that although there has been a decrease in visible separable fat consumption, there has also been an increase in "hidden fat" consumption through processed foods (e.g., baked goods), fried foods, and foods consumed in restaurants.[16] About 50% of the fats and oils in the food supply are used in processed foods.[16] Restaurant use of fats and oils has increased dramatically, primarily due to an increase in the number of restaurants serving fried foods.[16] As red meat consumption decreases, more meat is being purchased as nonseparable fat (e.g., ground beef, hotdogs) than separable fat.[16] Consumers may be unaware of the levels of fat in these products, since current grading standards are detrimental to consumer understanding of the fat content of meats.[16] Our results for individuals are consistent with these aggregated data; for example, franks/bacon and sweet grain products were major contributors to total intakes of fat, saturated fatty acids, and cholesterol. The challenge for nutrition educators is to help consumers identify these sources of hidden fats, both at point of purchase and in restaurants.

The use of high-fat additions appears to be an important determinant of total fat and saturated fatty acid intakes. Results indicate that women with the highest fat intakes consume regular salad dressing and butter/margarine more frequently and at greater serving sizes than do women with the lowest fat intakes. Women with the highest saturated fatty acid intakes consume butter/margarine more frequently, at greater serving sizes, and choose higher saturated fatty acid types more frequently, than do women with the lowest saturated fatty acid intakes. Nutrition education messages must emphasize that increasing consumption of salads, vegetables, and grain products as a means of reducing fat intake is effective only if high-fat additions are used sparingly.

Our results indicate that nutrition education messages about preparation methods such as breading, frying, and removing the skin of poultry would be beneficial to women aged 19 to 50. Among this population, it appears that meat/fish/poultry mixtures and grain mixtures are major sources of both fiber and total fat, saturated fatty acid, and cholesterol intakes, possibly due to sauces, butter/margarine, or cheese added to these foods in preparation. Messages about low-fat food preparation methods (e.g., use of low-fat rather than higher fat sauces and cheeses) should be devised specifically for these food groups.

Differences in the relative contributions of various food groups to fat intakes among different demographic subgroups can be used to refine educational messages. For example, substitution of low-fat for higher fat dairy products is more important for Hispanics and Whites; substitution of lower fat foods for franks/bacon is more important for Blacks. □

Acknowledgments

This study was carried out through the support of the Human Nutrition Information Service, US Department of Agriculture, Cooperative Agreement 58-3198-6-34. The research was conducted using the Cornell National Supercomputer Facility, a resource of the Cornell Theory Center, which is funded in part by the National Science Foundation, New York State, the IBM Corporation, and members of the Center's Corporate Research Institute.

1992 World Congress on Tuberculosis

The Fogarty International Center of the National Institutes of Health and the Centers for Disease Control, in collaboration with the National Institute of Allergy and Infectious Diseases, the National Heart, Lung and Blood Institute, the Food and Drug Administration, the US Agency for International Development, the World Bank, the World Health Organization, and the International Union Against Tuberculosis and Lung Disease, are pleased to announce that a World Congress on Tuberculosis will be held on November 16 to 19, 1992, in Bethesda, Maryland.

Invited to participate in the Congress are research scientists, tuberculosis control program officers, tuberculosis health care providers, and health officials, including Ministers of Health.

The Congress will focus on the goal of global tuberculosis control through basic and applied research in the diagnosis, treatment, and prevention of tuberculosis as well as behavioral and operational research. Program evaluation, quality assurance, and the epidemiologic, economic, and social aspects of tuberculosis will be discussed. Problems of special significance, such as the impact of HIV and drug resistance, will be addressed.

The Congress will feature addresses by leading national and international health officials; scientific presentations by leading investigators; and scientific poster sessions dealing with topics such as immunology, molecular biology, mycobacteriology, epidemiology, diagnosis, vaccine development, new drugs and therapy regimens, behavioral research, operational research, economic analyses, demonstrations/pilot projects, tuberculosis control programs, and program evaluation.

For additional information, or to obtain an official abstract form for presenting a poster, please contact the 1992 World Congress on Tuberculosis, Fogarty International Center, National Institutes of Health, Building 31, Room B2C32, Bethesda, Maryland 20892. Telephone number: 301/496-2516; Fax number: 301/402-2056.

Overcoming the Absence of Socioeconomic Data in Medical Records: Validation and Application of a Census-Based Methodology

Nancy Krieger, PhD

ABSTRACT

Background. Most US medical records lack socioeconomic data, hindering studies of social gradients in health and ascertainment of whether study samples are representative of the general population. This study assessed the validity of a census-based approach in addressing these problems.

Methods. Socioeconomic data from 1980 census tracts and block groups were matched to the 1985 membership records of a large prepaid health plan (n = 1.9 million), with the link provided by each individual's residential address. Among a subset of 14 420 Black and White members, comparisons were made of the association of individual, census tract, and census block-group socioeconomic measures with hypertension, height, smoking, and reproductive history.

Results. Census-level and individual-level socioeconomic measures were similarly associated with the selected health outcomes. Census data permitted assessing response bias due to missing individual-level socioeconomic data and also contextual effects involving the interaction of individual- and neighborhood-level socioeconomic traits. On the basis of block-group characteristics, health plan members generally were representative of the total population; persons in impoverished neighborhoods, however, were underrepresented.

Conclusions. This census-based methodology offers a valid and useful approach to overcoming the absence of socioeconomic data in most US medical records. (*Am J Public Health.* 1992;92:703–710)

Introduction

One problem frequently encountered by public health researchers and health planners in the United States is the absence of socioeconomic data in many widely used and routinely collected sources of health and disease information, such as medical records, disease registries, and vital statistics.[1,2] This omission is important, because social class, education, and income are known to influence both health status and use of health services.[1–7] Without these data, it is difficult not only to assess the role of socioeconomic factors in shaping the public's health, but also to ascertain whether a given study population is representative of the general population, and hence whether the study's findings legitimately can be generalized to the public at large.

To overcome this obstacle, various US investigators have sought to supplement individual-level health records with social class measures derived from an additional and easily available source of socioeconomic data, the US census.[1,8–20] In this approach, individuals are characterized by the socioeconomic profile of the immediate neighborhood in which they live (usually defined as the census tract), with the link provided by each person's residential address. To date, however, little research has examined the validity of this methodology,[1,8,21] including the degree to which it may result in ecologic fallacy (i.e., the erroneous inference of causal relations at the individual level on the basis of grouped data).[8,22–23]

To evaluate this census-based approach, I obtained health records with individual-level socioeconomic data from a large, multiethnic prepaid health plan and linked each individual's record to census-derived socioeconomic data acquired from two different geographic levels: (1) the census tract and (2) the census block group (a smaller and often more homogenous subdivision of the census tract that, on average, contains 1000 persons, as compared with the 4000 that typically reside in a census tract[24]). I then compared the association of both individual-level and census-based socioeconomic measures with four different health characteristics known to vary by race and socioeconomic position: hypertension,[2,25] height,[2,7,26] cigarette smoking,[2,7] and number of full-term pregnancies.[2,27] Census-based socioeconomic measures also were used to assess whether members of this health plan are representative of the surrounding general public. These analyses extend a smaller pilot project that compared individual, household, and census-derived social class measures as correlates of Black–White differences in reproductive history.[21]

Methods

Population

Study subjects consisted of all persons contained in the June 1985 computer-stored membership tape of the Kaiser Permanente Medical Care Program (KPMCP), Northern California Region (n = 1 924 995). Only data on age and gender are available for the total KPMCP membership; race/ethnicity and socioeco-

This paper was submitted to the Journal April 2, 1991, and accepted with revisions August 22, 1991.

nomic position are not ascertained. In 1987, the Medical Economics Department of KPMCP sent the June 1985 membership tape to be "geocoded" by a commercial firm, at a cost of $4.50 per 1000 records. This process assigned each individual a county code, census tract number, and block-group number based on the member's residential address and on geographic regions defined in the 1980 census.

A total of 1 593 388 KPMCP members (82.8%) were successfully geocoded. These members lived within 22 counties that were home to 98.8% of the total 1985 Northern California Region KPMCP membership. Missing or incorrect addresses, along with the absence of block-group codes in the 1980 census for three small Northern California counties (Amador, Lake, and Nevada), precluded fully geocoding the remainder. Members who were and were not successfully geocoded did not differ by gender and only differed slightly by age.

Census-Derived Data

Census tract and census block-group data from the 1980 US census were matched to each geocoded member's individual record. Each tract and block group was characterized by its social class and race/ethnic composition, and also by poverty and educational level.

Predominantly working-class tracts and block groups were defined as neighborhoods where 66% or more of the employed population belonged to the following census-based occupational categories: clerical and administrative support, sales, private household and other service occupations (except protective services), craft, transportation, and laborers. These occupations were selected because they disproportionately contain people who can be considered working class (i.e., employees who do not own their workplace, are not self-employed, and generally occupy subordinate positions at work).[21,28] The remaining census-defined occupations were considered non–working class: executive, administrative, and managerial; professional specialty; technicians and related support; protective service; and farming, forestry, and fishing (which includes farm owners and managers).

Impoverished tracts and block groups consisted of federally defined poverty areas, in which 20% or more of the population lived below the poverty line.[29] This economic indicator was chosen over the more commonly used, statistically defined measure of median family income because it takes into account a family's size and age structure and also pertains to the ability to buy a specified market basket of goods.[1,30,31] In 1980, the poverty level was set at $7356 for a family of two adults and two children.[29] Undereducated tracts and block groups were defined as regions where at least 25% of persons 25 years old or more had not completed high school.

Multiphasic Health Check-up Examination Data

Data from the multiphasic health check-up (MHC) examination were available for 17 200 persons contained in the geocoded June 1985 membership tape. This group represented 91.0% of the 18 904 KPMCP members who completed both the questionnaire and laboratory portions of the MHC examination in 1985 and who were KPMCP members as of June 1985.

Data obtained from the MHC examination included age at MHC examination, gender, race, years of completed education, occupation (current, if employed, or last occupation, if unemployed or retired), diastolic and systolic blood pressure, height, weight, cigarette-smoking history, and, for women, number of full-term pregnancies (NFTP). No data on income were collected. Using the same occupational groupings described above, social class was categorized as working class or non–working class. High blood pressure (HBP) was defined as diastolic ($\geq$ 90 mm Hg) and/or systolic ($\geq$ 145 mm Hg).[32] The Quetelet index (weight/height^2) served as a measure of body mass. The final sample consisted of 8674 White and 5566 Black KPMCP members included among the 17 055 persons in the MHC subset for whom race was identified.

Statistical Methods

Comparisons of demographic and health-related characteristics used the t test for continuous variables and the χ^2 test for categorical variables. The association of socioeconomic measures with the four health characteristics was determined by multivariate regression models run separately for the individual, tract, and block-group data. Analyses were performed with SAS programs for the personal computer.[33]

Multiple linear regression was used for health-related outcomes treated as continuous variables (height, NFTP). These models, in the form

$$y = \alpha + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k,$$

permit estimations of how much the dependent variable (y) increases or decreases with a unit change in each independent variable (x_k), as indicated by its coefficient β_k, controlling for the other independent variables in the model.[33,34] Logistic regression was used for dichotomous (yes or no) outcomes (HBP, smoking status). This method compares the probability (p) of experiencing an outcome given a particular exposure x_k, and is expressed in the form:[33,35]

$$\text{logit}\,(p) = \log\,(p/(1 - p)) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_k x_k.$$

The relative risk associated with a unit change in each independent variable x_k, again controlling for other independent variables included in the model, can be calculated as $e^{\beta k}$.

For each health characteristic, the same group of individuals was analyzed at the individual, tract, and block-group level, with all results adjusted for the same relevant individual-level risk factors (e.g., age and gender). These analyses are referred to as the complete models, since they included only those individuals missing no individual-level or census-derived data for any of the variables included at any of the three model levels. Total models permitted analyzing the effect of response bias due to missing individual-level socioeconomic data, and included persons missing these data but not census-level socioeconomic data or other relevant individual-level data. Contextual regression analyses,[36,37] which incorporate individual- and group-level measures of the same traits (e.g., individual class position and working-class composition of that individual's tract or block group), were used to determine whether the effects of individual socioeconomic position are modified by neighborhood conditions. These models used the individual- and census-level data in the form of a combined dummy variable.

On the basis of the results of these analyses, block-group characteristics of the total geocoded KPMCP membership were compared with those of the total population for all 22 counties combined. Because of the extremely large size of the KPMCP sample (1.6 million, representing 21.6% of the total population), statistical tests were not used. Instead, differences between these two groups are noted and assessed.

TABLE 1—Comparison of Demographic and Health-Related Characteristics

	White		Black		Comparison of Blacks to Whites[b] (95% Confidence Interval)
	Value[a]	% missing data	Value[a]	% missing data	
Age, y (mean ± SD)	51.8 ± 16.3	0.0	47.8 ± 15.4	0.0	−4.0 (−5.3, −2.7)

[e]Universe: all women (4700 Whites and 3358 Blacks).

Results

Characteristics of the MHC Subset

The extent of missing data varied considerably for the demographic and health-related traits recorded at the MHC examination (Table 1). With the exception of the few persons missing tract-level data, Black and White MHC study subjects did not significantly differ in the proportion missing data for any given trait. They did differ significantly, however, for every demographic and health-related outcome except one (percentage ever smoked) (Table 1).

Validation of Census-Based Socioeconomic Measures

Among persons included in the complete models, measures of social class and educational attainment at the individual, census-tract, and block-group levels yielded similar estimates for the association of these socioeconomic variables with, respectively, HBP, height, still smoking (among ever smokers), and NFTP (Table 2). Block-group models generally yielded tighter confidence intervals than tract models. Tract and block-group models both tended to underestimate slightly the socioeconomic associations observed at the individual level, and neither rejected the null hypothesis (no class effects) when this hypothesis was not rejected by individual-level models. For each outcome, Black–White differences were similarly reduced by adjusting for individual- and census-level socioeconomic measures (Table 2).

Use of Census-Based Measures to Assess Respondent Bias

Adding persons who lacked individual- but not census-level socioeconomic data markedly increased the number of available subjects (Table 3). These additional persons tended to be older, and were more likely to be women and to reside in predominantly working-class, impoverished, and undereducated block groups, than persons included only in the complete models.

Evidence of respondent bias in the complete models was most apparent for Black–White comparisons concerning HBP and NFTP (Table 3). The adjusted relative risk of HBP among Black as compared with White MHC study subjects was 12% lower in the total than in the complete models (1.5 vs 1.7), while the relative excess of NFTP was 20% lower (0.4 vs 0.5). As would be expected, including substantially more persons in the total models produced tighter confidence intervals.

Contextual Analyses

Contextual regression analyses were conducted only with persons included in the complete models, since only these subjects possessed both individual- and census-level social class or educational measures. Suggestive contextual effects for both measures were observed for all four outcomes in both tract and block-group models. For example, as shown in Table 4, working-class women who lived in non–working-class block groups had virtually the same number of full-term pregnancies as non–working-class women who likewise lived in non–working-class block groups, whereas working-class women who lived in predominantly working-class block groups had 0.4 more full-term pregnancies than this latter group ($P < .05$).

Application of the Census-Based Methodology

[b]HBP defined as diastolic (≥90 mm Hg) and/or syatolic (≥ 145 mm Hg).

vealed few differences with regard to race/ethnic composition (Table 5). Although a comparable proportion of KPMCP members and the general population lived in predominantly working-class block groups, KPMCP members were somewhat less likely than the general public to live in impoverished and undereducated block groups (Table 6).

Discussion

The census-based methodology of supplementing individuals' health records with socioeconomic data from their census block groups appears to offer a valid and useful approach to overcoming the absence of socioeconomic data in US medical records. Among 14 240 Black and White men and women who took the KPMCP MHC examination, individual, tract, and block-group measures of social class and education provided highly comparable estimates of association with four diverse health characteristics known to exhibit marked social class and race/ethnic gradients[2,7,25–27]: hypertension, height, smoking, and number of full-term pregnancies.

Beyond this, the use of census data permitted assessing the effect of respondent bias introduced by missing individual-level data, and also allowed contextual analyses to be conducted. These analyses indicated that census data may augment, and not simply approximate, individual-level socioeconomic data. Lastly, the census-based methodology provided a straightforward and relatively inexpensive way of ascertaining whether the KPMCP membership is representative of the surrounding general population, with the findings recently corroborated by the 1989 to 1991 California Risk Factor Surveillance Study (N. Gordon, written communication, February 1991).

Comparison with Other Studies Using Census-Derived Data

To date, very few US studies have compared individual-level and census-derived socioeconomic indicators as correlates of health status.[1,8,21] The greater heterogeneity among residents of census tracts as compared with block groups, however, has long been of concern,[38,39] with some evidence suggesting that block-group data can identify pockets of poverty or affluence not apparent at the tract level.[40] Also bolstering this study's findings are the results of a related pilot project carried out in Alameda County, California.[21] This study of 51 Black and 50 White women found that census block-group measures of social class and poverty closely approximated individual-level measures as correlates of women's reproductive histories, whereas comparable data from the tract level performed less well. Contextual analyses likewise indicated the importance of categorizing women by both individual-level and block-group–level socioeconomic characteristics.[21]

Additional evidence regarding contextual effects and health status stems from another Alameda County study that found that persons who lived in poverty areas were 1.7 times more likely to die during 9 years of follow-up than were persons living in nonpoverty areas, even after controlling for a large number of demographic, physiological, and psychosocial variables.[41] Other US research has observed contextual effects for such diverse phenomena as voting behavior,[42–43] students' test scores,[44] adult participation in community-based organizations,[45] and social problems associated with residential segregation[46] (e.g., Black professionals in the United States are more likely to live in working-class neighborhoods than their White peers, such that analyses "controlling" for only individual-level class differences fail to capture important neighborhood-related differences in socioeconomic position).

Several British investigations likewise have found that area-based measures of deprivation and individual-level social class data detect comparable social gradients in health outcomes.[47–53] As noted by Carstairs and Morris,[48] and by Alexander et al.,[50] these area-based measures possess the additional advantage of being able to evaluate the relationship between health status and socioeconomic position among persons not easily classified by traditional occupation-based class measures (e.g., children, students, and adults not in the active labor force). In these studies, area-based measures of deprivation also revealed intraclass mortality gradients,[49–51] providing additional evidence of contextual effects.

Potential Biases Affecting the Census-Based Methodology

The census-based methodology is not without flaws. First, it requires that individuals have a residential address, and that this address be located within a census-defined tract or block group. In this investigation, 17% of the KPMCP membership could not be geocoded to the block-group level. Despite their similarity in age and gender composition, members with and without block-group data may have differed with regard to other sociodemographic characteristics (e.g., urban vs rural residence), thereby introducing bias. Manual searches on addresses not geocoded by computerized procedures, however, can reduce the percentage of persons not assigned a block-group number to under 5%.[14,15,21] Moreover, beginning with the 1990 census, block-group codes were assigned to the entire nation.[54]

Second, census data might not accurately characterize the demographic context of study subjects because of the decennial nature of census data[55] and also because of the undercount, which chiefly affects poor people and people of color.[55–58] Because population growth and migration can alter a neighborhood's composition,[55] this census-based methodology should be used only for residential addresses falling within 5 years of the closest census. The undercount, in turn, most likely would dilute the association between health status and block-group socioeconomic measures, since it produces conservative estimates of the number and hence proportion of poor persons and people of color.[55–58]

A third concern pertains to ecologic fallacy, which can produce inflated estimates of individual-level associations.[22–23] Although this study used grouped data to characterize individuals, the census-based methodoiogy presented here is not affected by the "classic" type of ecologic fallacy, in which both the dependent and independent variables are grouped data and underlying factors associated with the grouping process confound the results.[22–23] Instead, individual-level dependent variables were analyzed in conjunction with census-based independent variables. To minimize heterogeneity in the census unit, however, it may be preferable to use block-group rather than tract data, if available.[21,38–40]

A final caveat applies to the contextual analyses. Only a limited number of socioeconomic and health-related variables were used in these analyses, since the purpose was to evaluate the association between different socioeconomic factors and health characteristics, as opposed to elucidating the pathways through which these factors exert their effects. Yet, as noted by some critics, if individual-level models are not fully specified, seemingly significant contex-

tual effects may be spurious, with the contextual variables only "explaining" variance that could be better accounted for by additional individual-level data.[37,59] Even so, the plausible nature of the observed contextual trends suggests that this technique may provide a useful means by which to avoid "individualistic fallacy,"[22] that is, the assumption that individual-level data are sufficient to explain social phenomena, including a population's level of health and disease.[60]

Significance and Usefulness of the Census-Based Methodology

The importance of validating this census-based approach to measuring socioeconomic position is underscored by the numerous US studies that, in the absence of individual-level social class data, have used census-derived data from people's immediate neighborhoods in conjunction with individual-level health data to describe, analyze, or control for social gradients in various health outcomes.[9–20] These include investigations regarding race/ethnic differences in cancer incidence and survival,[9–16] homicide,[17] and childhood diseases,[18] as well as studies examining intraurban variation in mortality.[19,20] All have observed significant associations between people's health status and the socioeconomic conditions of the neighborhoods in which they live, and all have expressed concerns regarding the use of census-derived data. The results of this study and comparable research[21,47–53] indicate that these prior findings most likely are legitimate and probably underestimate the effect that would have been observed were individual-level social class data available.

In sum, the census-based methodology presented in this study provides a valid and useful approach to overcoming the absence of socioeconomic data in most US medical records. Because census data are readily available to all US public health researchers and geocoding is not expensive, this methodology easily can be used with any existing data set that contains residential addresses. By offering a measure of socioeconomic position that is applicable to all persons, regardless of age, gender, or employment status, this census-based approach also can greatly assist in both reducing and evaluating response bias resulting from incomplete or inaccurate individual-level socioeconomic information. Other possible uses include ascertaining whether a study sample is representative of the general public, whether a given program is reaching its intended population, and whether socioeconomic factors contribute to small-area variation in health status and health service use patterns. Lastly, in those cases where individual-level data are available, this methodology permits use of contextual analysis, thereby offering new avenues to investigate the diverse routes by which social gradients in disease are produced and maintained.

Apart from raising new questions about social context, the most important contribution of the census-based methodology may be in furnishing US researchers with the means to construct age-specific incidence, prevalence, and mortality rates, stratified by consistent area-based measures of social class. This can be accomplished for most disease outcomes, since denominator data typically are census derived and can be classified according to the same block-group measures.[14] By focusing attention on social gradients in disease within, and not only between, different race/ethnic groups within the United States, such data could potentially reinvigorate, if not reorient, efforts to understand as well as eliminate socially determined disparities in health. □

Acknowledgments

Ownership and Performance of Outpatient Substance Abuse Treatment Centers

John R. C. Wheeler, PhD, Huda Fadel, MPH, MAE, and Thomas A. D'Aunno, PhD

ABSTRACT

Background. Little is known about the organization and performance of outpatient substance abuse treatment (OSAT) centers. We examine several performance measures of OSAT units, including clients treated, services provided, revenue sources, financial performance, and access to care, in relation to ownership of the center.

Methods. Data were drawn from a national random sample of 575 OSAT centers (85.8% response rate) participating in a telephone survey conducted in 1988. Analysis of variance by ownership was conducted on each performance measure, with differences subjected to tests of statistical significance.

Results. Descriptive results show that major funding sources differ by ownership. Private for-profit centers generate higher profits, charge higher prices, and achieve higher levels of financial performance than public and not-for-profit centers. Public centers provide better access to care for persons who are unable to pay.

Conclusions. There appear to be substantial and interrelated differences by ownership type in the financing and operation of OSAT units. (*Am J Public Health.* 1992; 82:711–718)

Introduction

Substance abuse is a major health hazard in the United States, accounting for over $2.4 billion in treatment and prevention expenditures in 1989.[1] The National Drug Control Strategy appropriated approximately $925 million for treatment interventions in fiscal year 1990, representing a significant increase in public commitment to reduce drug demand.[2] But despite this high level of investment, little is known about the outpatient substance abuse treatment (OSAT) organizations that provide most of the treatment. Specifically, there is a lack of up-to-date information regarding the nature of care provided in OSAT units, the revenue sources and financial performance of the programs, or even their accessibility to persons in need of services. This paper examines these issues using a nationally representative sample of OSAT organizations.

A brief overview is useful for understanding the substance abuse treatment system. This paper focuses on outpatient providers who currently treat the vast majority (more than 85%) of clients in the substance abuse treatment system.[3] Two treatment modalities predominate: outpatient methadone maintenance and outpatient drug-free therapy. In the first, treatment begins with the use of a synthetic narcotic (methadone) being substituted for the abuse of opioid drugs, enabling the client to taper off gradually and eventually eliminate drug use. In the second, a combination of individual and group counseling, psychotherapy, and supervision is used to eliminate drug use. The provision of both modalities has grown rapidly since the 1960s owing to government and private funding, but drug-free therapy is currently the prevalent treatment mode.

Much of the substance abuse treatment research has focused on clients and particularly on what happens to individuals who undergo treatment. Outpatient substance abuse treatment is less well understood, however, on an organizational level. Although most programs use similar treatment methods (i.e., individual, group, and family therapy) to produce OSAT care, other organizational differences between providers can be expected to result in different modes of operation and performance.[4] The question is, what are some of these organizational characteristics and how do they relate to observed performance in OSAT units?

One potentially important characteristic is the ownership status of the treatment unit—i.e., whether it is owned and operated on a private for-profit (FP), private not-for-profit (NFP), or public basis. The salience of ownership status derives from how that status is connected with the organization's objectives, such as profit maximization, access to care, prestige, patient outcomes, etc. At one theoretical extreme, FP firms operate to maximize the wealth of the owners. At the other extreme, public firms seek to promote social welfare. In between these two extremes, NFP firms seek to achieve both social and private objectives within a private context.[5]

The authors are with the University of Michigan's Institute for Social Research and School of Public Health in Ann Arbor.

Requests for reprints should be sent to John R. C. Wheeler, School of Public Health, University of Michigan, Ann Arbor, MI 48109-2029.

This paper was submitted to the Journal September 18, 1990, and accepted with revisions September 20, 1991.

Economic theory predicts that FP firms will behave differently from NFP or public firms because of the presence of clearly defined owners. These owners and their managers are rewarded for operating efficiently; i.e., excess profits are distributed. Incentives for efficiency tend to be weaker in NFP and public firms because of a lack of clear ownership and the nondistribution of profits.[6] In practice, however, organizational performance may or may not differ, depending not only on organizational objectives but also on incentives provided by funding sources, differences in services provided, characteristics of clients treated, influences of program staff, and other market characteristics.[7]

Many research studies have examined the association between ownership and organizational performance in health care. Several hospital studies have suggested important and substantive differences in the behavior of NFP and FP firms. Findings include the production of costlier and higher priced care in FP hospitals,[8] higher prices and profits in FP hospitals,[9] better access in NFP hospitals,[8,10] and more charity care in NFP hospitals.[8,11] Other studies conclude that NFP hospitals are less efficient than FP hospitals, after adjustment for tax subsidies.[12] Finally, there are still others that report no important differences between the two ownership types.[13] Similarly mixed results have been reported for other types of health care organizations.

In the substance abuse field, the public sector has traditionally assumed major responsibility for the operation of treatment programs. The role of the private sector has been increasing, however—especially that of FP firms. To a great extent, the growth in private sector ownership of OSAT organizations is simply a part of the general trend in health care toward increased private delivery of services.[14,15] It also reflects specific public policies in the 1980s to increase private sector participation in the war on drugs, such as the 1984 national strategy for drug abuse policy.[16] As in other health sectors, however, the relationship between increasing privatization and the effectiveness and efficiency of substance abuse treatment is not well understood. Further study is needed to assess the benefits and potential costs of private sector ownership in this field.

This paper describes OSAT clients and service characteristics, funding for OSAT programs, the programs' financial performance, and the accessibility of their services. Differences in organizational performance that are related to ownership status are highlighted and discussed.

Methods and Measures

Sample

The data for this paper were collected from a national study of OSAT organizations that was supported by the National Institute on Drug Abuse. The study was conducted in the fall of 1988 by the Institute for Social Research at the University of Michigan. A random sample of 670 OSAT units was selected from a total population of 6851 such units in the United States in 1988. The sample was stratified according to treatment modality (methadone or drug free), treatment setting (mental health center, hospital-based program, freestanding facility) and ownership status (private FP, private NFP, and public). Five hundred and seventy-five units participated in the survey, yielding a response rate of 85.8%. The response rate for private units (both FP and NFP) was 88.0%; for public units, 81.7%. Each unit's administrative director and clinical supervisor were asked to complete telephone surveys. Directors provided information about their unit's financial status and services, and clinical supervisors provided information about personnel, client characteristics, and substance abuse problems. All information was collected for the unit's most recent complete fiscal year.

Measures

Organizational performance was represented by four sets of multiple measures (see Appendix).

Analysis Method

Analysis of variance tests were conducted on each performance measure, using ownership status as the stratification variable. Differences in performance across ownership types were then subjected to statistical significance tests.

Results

Clients and Services

Measures that describe and differentiate the units in terms of client and service characteristics are displayed in Table 1. More than 69% of the units are devoted exclusively to drug-free treatment, leaving 31% that provide any amount of methadone therapy. By ownership strata, 74% of NFP, 65% of FP, and 63% of public units are drug-free treatment centers.

Classification of clients in treatment according to their specific substance abuse problem is difficult largely because of prevailing patterns of multiple substance use. Nevertheless, clients can be generally categorized as to whether they are primarily alcohol or drug abusers. The primary problem for more than 40% of clients at treatment units is alcohol abuse whereas 51% are primarily drug abusers. (The remaining 9% are clients who could not be assigned to either primary category.) These patterns do not differ significantly by ownership.

Abuse of specific types of substances, singly or in multiple combinations, is common, even for those clients whose primary problem is alcohol addiction. Treatment units overall reported that, on average, 23% of their clients have problems with heroin abuse whereas 27% abuse cocaine. For-profit units tend to have the highest percentage of clients with heroin problems (34%), followed by public units (25%) and NFP units (20%). A similar pattern also holds for cocaine abuse: the percentage of cocaine abusers is highest in FP units (30%), followed by public units (27%) and NFP units (26%). Public units report the highest percentage of multiple drug abusers (55%) whereas FP units report the lowest (44%); these differences are statistically significant. These measures indicate that the major substance abuse problems presented at OSAT units may be similar in nature. The measures are too broad, however, to make conclusions regarding client case-mix severity or service intensity among different units.

Treatment units vary significantly in terms of the mix of therapy types, length of therapy sessions, and group size. On the whole, individual therapy accounts for 78% of all treatment sessions and 72% of all treatment hours provided. Public units produce the highest proportion of individual therapy sessions and hours, followed by private NFP and FP units. The average lengths of therapy sessions show inconsistent patterns that may reflect underlying differences in product mix among the units. Individual therapy sessions are longest in NFP and public units; however, group therapy sessions are longest in FP units. This may reflect the larger treatment group sizes seen at FP units. It may also indicate other characteristic differences, such as type of group therapy provided. In addition, patients in FP units attend group therapy more times per week than patients at other types of units.

Revenue Sources

Approximately two-thirds of OSAT revenue comes from public sources (see Table 2). The bulk of this money comes directly from state government sources, with the remainder coming largely from city and county government. Only a small percentage was reported as direct revenue from the federal government. Approximately one-third of total revenue comes from private sources, principally as client out-of-pocket payments and payments from private insurance companies.

Sources of financing differ significantly by ownership category. Private FP units receive 84% of their revenue from private sources. Most of this money (47%) comes from patient out-of-pocket payments, with private insurance being the second largest source (37%). Only 11% of FP units' revenue comes from government sources. In sharp contrast, public treatment units receive 80% of their revenue from public sources and only 19% from private sources. In NFP units, the mix of revenue sources is similar to that for the study sample as a whole, with approximately two-thirds of revenue coming from public sources and one-third coming from private sources.

The way treatment is funded relates to two important issues. First, financing source differences may reflect systematic differences in the types of clients seen by the treatment units, in terms of clients' social and economic resources. Second, each funding source may provide revenue in several ways. The basis upon which units receive revenue—e.g., fee for ser-

vice, capitation, lump-sum grant, etc.—may provide diverse incentives for the organization of treatment.

Financial Performance

Table 4 presents the financial performance of OSAT operations. For the whole sample, total expenses per therapy hour and per therapy session are $62 and $81, respectively. Expenses for salary and wages are $47 per therapy hour and $58 per therapy session. On average, salary and wages comprise approximately three-quarters of total OSAT expenses—a high percentage being devoted to service provision as opposed to overhead and other expenses.

These financial measures differ significantly by ownership type. Public units have higher costs per therapy hour than either FP or NFP units. For-profit units have lower costs per session than both NFP and public units. In the absence of client outcome data, inferences regarding "efficiency" differences among units cannot be made, nor can inferences regarding cost per client, as services and clients may vary across units.

Average OSAT revenue per therapy hour and per therapy session for the whole sample are $66 and $80, respectively. Analysis by ownership types indicates that FP units receive lower amounts of revenue per unit of output than public and NFP units. On the other hand, FPs typically charge much higher prices for individual, group, and family therapy sessions than either NFP or public units. Because therapy sessions often differ in length, a standardized measure was created to compare prices based on a 60-minute therapy hour. The results (not shown) confirm the finding that FP units charge significantly higher prices than NFP and public programs.

It is not uncommon in health care organizations for prices charged to differ from revenues received. A firm's charges are usually higher than the revenues it receives per unit of service because of discounts granted to third-party payers, uncompensated care, etc. There is, however, an apparent contradiction in the fact that the prices charged by the FP units are relatively higher while the revenues per service received are lower, whereas the relation is reversed for public units, which charge lower prices but receive higher revenues per service. A principal explanation has to do with the way in which units receive revenue. For example, FP units receive most of their revenue from client fees, whereas the public units receive substantial revenue in the form of block grant subsidies. This suggests that pricing behavior may be related to incentives embedded in the way a unit receives its revenue. That is, revenues that are not received from clients or based on organizational performance, such as block grants, allow organizations to charge lower prices to clients.

Profit margin, indicating the business efficiency of unit operations, is the final measure of financial performance (see Table 3). For the sample as a whole, treatment units earn an average profit margin of 2%. However, profit margins differ widely across ownership types. For-profit organizations earn a return of 8% of revenues whereas public units break even. Not-for-profit organizations earn profits of 2% of revenues. Comparison of FP performance with that of other units shows significant differences, whereas compari-

sons of profitability between NFP units and public units do not.

Accessibility

Table 4 summarizes the extent to which OSAT units promote access to and equity of service provision. In the full sample, an average of 26% of clients were unable to pay for the care they received; the measure ranges from 8% for the FP units to 32% for the public units. The percentage of clients seen who pay a reduced fee is 47% for all units. Again, FP units treat a much smaller percentage of patients under reduced fee arrangements. Taken together, the percentage of clients who either pay nothing or pay a reduced fee for care received is 82% for public units, 74% for NFP units, and 23% for FP units.

Only 2% of all patients are turned away because they are unable to pay for services. Public units turn away virtually no clients whereas FP units turn away 7% of potential clients.

The length of waiting lists for care, in terms of the numbers of clients in the queue and days of waiting time, is an important measure of whether the existing system is meeting patient needs. The average waiting list for all units is 16 clients and 10 days to begin treatment. Mean waiting lists are somewhat longer for public units and somewhat shorter for FP units although the differences are not significant. An additional analysis (not shown), which relates the number of potential clients on the waiting list to the size or capacity of the unit, does not indicate ownership differences.

Discussion

The OSAT system consists of diverse provider organizations. This paper has categorized treatment units by ownership and found that significant differences characterize the units in terms of clients treated, services offered, funding sources, financial performance, and accessibility.

One of the most critical results is the significant difference in major funding sources by ownership type. This finding is especially important because of the relationship between funding sources and several organizational outcomes—that is, types of clients treated, service mix provided, financial performance, and extent of access to services. For example, even though OSAT programs may not differ significantly in terms of treatment modality or major types of substance problems treated (Table 1), differences in their major revenue sources (Table 2) suggest that the clientele may, in fact, differ between the units. Programs receiving most of their revenue from private insurance or out-of-

pocket payments are likely to be treating a more affluent clientele. Differences in clients' economic and social resources have been associated with differences in drug problem severity.[17] However, detailed information on client severity and outcomes are not available from the current study. Further analysis that controls for patient characteristics needs to be done.

Associated with differences in funding sources are alternative payment methods—i.e., how units receive revenue. Certain funding sources, such as some third-party payers, often impose constraints on the types or amount of services delivered or on the types of personnel used to produce services. In addition, the basis upon which revenue is received—e.g., fee for service, capitation, or lump-sum grant—varies by funding source. Incentives embedded in various payment arrangements have implications for service organization and allocation. For example, it has been found that per visit reimbursement encourages more sessions per course of treatment on average than a lump-sum reimbursement arrangement in OSAT centers.[18]

Additional findings from the study further indicate that ownership is an important determinant of OSAT organizational outcomes. It was reported that FP units are operated at a higher level of profit than are NFP and public units (Table 3). There are several possible explanations for this higher profitability, the most obvious being that FP units operate under a different set of objectives than do public and NFP units. It is also possible that FP units provide services more efficiently; however, this cannot be determined without controlling for client outcomes and product mix. Finally, as mentioned above, the fact that FP units rely heavily on private revenue sources may also be a major influence on their behavior and outcomes.

Because public and NFP units accept a higher percentage of nonpaying and reduced-fee clients (Table 4), they appear to do more to facilitate access to care for persons whose means of payment are limited. Such behaviors are consistent with organizational and economic theories that state that these types of firms exist to provide public or social goods that the private FP sector may underprovide.

There appears to be substantial differences in the financing and operation of OSAT units related to ownership type. Generally speaking, these differences are more striking than those reported in the literature for other health care providers. What is not clear is why these differences exist. In that respect, this paper probably raises more questions than it answers. One obvious set of questions concerns whether the observed differences in revenue sources, finances, accessibility, and service types are directly attributable to ownership or are more closely tied to other characteristics that happen to be associated with ownership. For example, are differences in financial performance due to the fact that FP organizations may have objectives that differ from those of public units or are they due to differences in the constraints faced by the two ownership types relating to primary revenue sources, clients served, or a combination of the above?

Another important set of questions relates to the meaning of other differences found. For instance, does the fact that FP units provide a lower percentage of individual therapy have any relationship to the overall quality of care delivered? Likewise, do the pricing differentials for services between units by ownership type reflect underlying differences in the types of therapy delivered, or do they simply reflect efficiency differences? Future research will be necessary to answer these and similar important questions. □

Acknowledgments

The authors wish to express their gratitude to David M. Klingel, William C. McCaughrin, Richard H. Price, and two anonymous reviewers who offered conceptual and technical assistance in the development of this manuscript as well as thoughtful reviews of earlier drafts.

APPENDIX—Measures of Organizational Performance

Clients and Services

Treatment modality: percent of drug-free units[a]
Primary substance abuse problem[b]
- Percent of clients whose primary problem is alcohol abuse
- Percent of clients whose primary problem is drug abuse

Abuse of other drugs[c]
- Percent of clients abusing heroin
- Percent of clients abusing cocaine
- Percent of clients abusing multiple drugs

Service mix
- Individual therapy as percent of total therapy sessions
- Individual therapy as percent of total therapy hours

Service characteristics
- Minutes per individual therapy session
- Minutes per group therapy session
- Minutes per family therapy session
- Clients per group therapy session
- Number of group therapy sessions per client per week
- Number of clients per family therapy session

Revenue Sources

Government
- Federal
- State
- Local

Private
- Insurance[d]
- Out-of-pocket payments
- Donations

Notes.
1. All revenue sources are expressed as a percentage of total revenue.
2. Federal grants programs administered by state governments were counted as state government revenue.

Financial Performance

Total expenses per therapy hour
Total expenses per therapy session
Salary and wages expenses per therapy hour
Salary and wages expenses per therapy session
Total revenue per therapy hour
Total revenue per therapy session
Price per individual therapy session
Price per group therapy session
Price per family therapy session
Profit margin[e]

Notes.
1. Expenses, revenues, salary, and wages are specific to OSAT care.
2. Therapy hours are total number of hours of individual, group, and family therapy.
3. Therapy sessions are total number of sessions of individual, group, and family therapy.

Accessibility

Percent of clients unable to pay for care received
Percent of clients paying reduced fee for care received
Percent of clients turned away because of inability to pay
Number of potential clients on waiting list for treatment
Number of days on waiting list for treatment.

[a]Programs providing any amount of methadone therapy were classified as methadone units.
[b]Refers to the *primary* substance abuse problem treated. The sum of alcohol and drug abuse is 100%.
[c]Refers to abuse of drugs independent of the primary substance abuse problem. May be a primary or secondary problem. The sum of the percent of clients abusing heroin minus the percent of clients abusing multiple drugs is *not* equal to the percent of clients whose primary problem is drug abuse.
[d]Includes commercial insurance and Blue Cross/Blue Shield plans. Medicare payments are categorized as federal revenue, and Medicaid payments are categorized as state revenue.
[e]Defined as net income divided by total revenue.

Israeli/Palestinian International Conference on Water

The first Israeli/Palestinian International Academic Conference on Water will be held October 20 to 23, 1992, in Jerusalem/Bethlehem at the Tantur Conference Center. The Conference program will include lectures, roundtables, and discussion groups on the water resources conflicts between Israelis, Palestinians, and others in the area and on possible solutions.

Specific topics to be discussed: history of the water conflicts of the region; present status of water resources in the region; role of international water law; technical options for increased water resources; regional projects for importing water and/or desalination; nonconventional water sources/water recycling, cloud seeding, fossil water, brackish water; efficient water use and conservation; environmental quality management of shared water resources; joint commissions for monitoring, control, and management of shared international water resources and projects; technical assistance; international financing; and other topics.

The conference language is English, and the conference is open to scientists, engineers, and policymakers from all countries.

Low-cost hotel facilities are available at the Tantur Conference Center, which is conveniently located on the main road between Jerusalem and Bethlehem.

For further information write to either one of the Conference Cochairs and sponsoring organizations: Cochair Dr. Jad Isaac, Applied Research Institute, PO Box 860 Bethlehem, Via Israel (Fax: 972-2-741889); Cochair Professor Hillel Shuval, Truman Institute for the Advancement of Peace, The Hebrew University of Jerusalem, Jerusalem, Israel (Fax: 972-2-322545/666804).

Home Apnea Monitoring and Disruptions in Family Life: A Multidimensional Controlled Study

Elizabeth Ahmann, ScD, RN, Louise Wulff, RN, ScD, and Robert G. Meny, MD

ABSTRACT

We used data from telephone interviews and mailed questionnaires to examine 12 aspects of family life among 93 families with infants considered at high risk for sudden infant death syndrome and on home apnea monitors and a matched comparison group with infants not requiring monitoring. Using logistic regression to control confounding variables, we found that case mothers were at an increased risk of poor health, but we found no other significant differences in family life between the two groups. (*Am J Public Health.* 1992;82:719–722)

Introduction

The presumed association between apnea and sudden infant death syndrome (SIDS) has led to the use of home apnea monitors for diagnostic and preventive purposes. According to the Congressional Office of Technology Assessment, as many as 45 000 infants are on home apnea monitors,[1] a prevalence of 11 to 12.4 monitored infants per 1000 live births.[2]

Despite its prevalence, home apnea monitoring remains controversial, in part because of concern about its possible detrimental effects on the family.[3–5] While descriptive studies[6–10] have suggested effects including parental fatigue, anxiety, social isolation, and depression, analytic studies[11–14] have had varied and conflicting results.

To provide a more comprehensive and well-controlled examination of family life than in previous studies of monitored infants, we conducted a cross-sectional study of family members' health and behavior; intrafamilial roles, relationships, and functioning; and family–social relationships.

Methods

All case families were participants in two monitoring programs providing support and follow-up similar to that recommended by the National Institutes of Health.[5] We collected data from 93 families of infants considered at high risk for SIDS and on home monitors (80.9% response rate) and 86 comparison families with infants not requiring monitoring (84.3% response rate). Comparison families, identified from birth/nursery records, were matched to cases on infant age, race, and sex, as well as maternal marital status, parity (1 vs >1), and health insurance status. Institutional review boards at each site approved the study.

A higher percentage of case respondents (63%) than nonrespondents (31.8%) had commercial insurance ($\chi^2 = 7.379$, $df = 2$, $P = .025$). Respondents and nonrespondents did not differ significantly on infant age, gestational age, race, sex, reason for monitoring, or maternal marital status or parity.

Telephone interviews with mothers provided data on potentially confounding variables (Tables 1 and 2). Questionnaires mailed separately to mothers and fathers included scales measuring 12 dependent family life variables: the Parental Depression, Parental Health, Sense of (parenting) Competence, Attachment (to infant), Restrictions of (parenting) Role, Relationship with Spouse, and Social Isolation subscales of Abidin's Parenting Stress Index[15] (Chronbach's alpha reliabilities[16] ranged from 0.58 to 0.99); the Kansas Marital Satisfaction Scale[17] (alpha of 0.95); the frequency scale of Eyberg's Child Behavior Inventory[18] (sibling behavior) (alpha of 0.99); and three scales developed specifically for this study to measure the quality of both the parent–

**$t = -2.23$, $P = .0268$.

infant (alpha of 0.78) and parent–sibling (alpha of 0.85) relationships and ease of daily activities (alpha of 0.82). Preliminary reliability and validity testing of these scales supported their use.[2]

Scores on scales measuring dependent variables were dichotomized at predetermined cutoff points to distinguish normal or optimal functioning from at-risk or suboptimal functioning. We examined confounding separately for each dependent variable. We then used logistic regression to evaluate the relationship between case-comparison status and each dependent variable while controlling for confounders. We conducted separate analyses for mothers and fathers. SAS, version 5,[19] and PROC LOGIST[20] were used.

Results

At the time of the study, case infants had been monitored a mean of 45 days (median = 40, mode = 30). They were monitored for the following reasons: (1) SIDS sibling (5.4%); (2) severe apparent life-threatening event (20.4%); (3) less serious event or abnormal pneumogram or polysomnogram (full-term infants) (24.8%); or (4) less serious event, usually apnea of prematurity continuing up to approximately the time of discharge (preterm infants) (49.5%). Reason for monitoring, presence or absence of additional medical problems, gestational age, frequency of reported alarms, and frequency of need to stimulate the infant to breathe were not significantly associated with any of the dependent variables.[2] As a result, heterogeneity in these factors was considered a strength rather than a weakness of the study.

The mean age of the infants was 3.0 months. Most were White (69.9%) and male (58.1%). Most of the mothers were married (63.4%), had more than one child (55.4%), and had commercial insurance (63.0%).

Case and comparison groups differed on only three of many potentially confounding variables examined: gestational age, days hospitalized at birth, and satisfaction with social support (Tables 1 and 2).

Among mothers, gestational age confounded the relationship between case-comparison status and one dependent variable, relationship with baby. Satisfaction with social support was a confounder in relation to several of the dependent variables: parental health, parental sense of competence, parental role restriction, relationship with spouse, marital satisfaction, and social isolation. No other study variables were confounders among mothers, and none were confounders among fathers.

When confounders were controlled using logistic regression, case and comparison mothers differed significantly on only one dependent variable: parental health (Table 3). Case and comparison fathers did not differ significantly on any of the dependent variables (Table 4).

TABLE 3—Mothers: Beta Coefficients from Logistic Regression of Case-Comparison Group and Confounders on Dependent Variables

Discussion

The difference between the scores of case and comparison mothers on the Parental Health measure indicates a greater risk of poor health among mothers of monitored infants. We found no other significant differences between case and comparison families based on either maternal or paternal responses.

Poor health, fatigue, and somatic complaints have been reported among mothers of monitored infants.[6,9,14] While McElroy et al.[13] found no differences in somatization among case and comparison mothers, study infants were no longer being monitored at the time somatization was measured. In this study, only two of the five items on the Parental Health measure distinguished case vs comparison mothers, and these were global health measures rather than questions about specific symptoms (see Appendix). It has not been established whether global health measures are accurate indicators of physical health or are more precisely interpreted as measures of a sense of well-being.[21–25] Regardless, since case and comparison infants in this study differed in the need for home monitoring as well as in the use of monitors, and prior maternal health status was not measured, poor maternal health cannot be definitively attributed to the experience of home monitoring.

The absence of significant differences, other than maternal health risk, between case and comparison families indicates that the majority of families in supportive monitoring programs have adequate resources enabling them to cope well with the demands and stresses of home monitoring and to function capably in many aspects of family life. □

Carrier Screening for Cystic Fibrosis: A Pilot Study of the Attitudes of Pregnant Women

Jeffrey R. Botkin, MD, MPH, and Sonia Alemagno, PhD

ABSTRACT

We surveyed the attitudes of a consecutive sample of 306 pregnant Caucasian women toward carrier screening for cystic fibrosis. Of the 214 respondents, 98% said that screening should be offered before pregnancy, and 69% said they would accept carrier screening during pregnancy. Twenty-nine percent of the respondents indicated a willingness to terminate a pregnancy if the fetus were found to have cystic fibrosis. We conclude that carrier screening is of interest to pregnant women, although interest in terminating a pregnancy because of screening results may be limited. (*Am J Public Health.* 1992;82:723–725)

Introduction

The identification of the gene responsible for cystic fibrosis (CF) offers the capability of performing carrier screening for CF in the general population. Cystic fibrosis is an autosomal recessive disease and is the most common lethal genetic disease in Caucasians. The incidence at birth is approximately 1 per 2500 Caucasian infants. The carrier (heterozygote) frequency is approximately 1 in 20 to 25 Caucasians in North America.[1] Carriers for CF are asymptomatic; however, individuals may be interested in knowing their genetic status in order to make informed reproductive decisions.

Carrier screening for CF in the general population is controversial.[2–5] The initiation of carrier screening in the general population has been inhibited by the relatively low sensitivity of the current technology for screening[6–8]; to date, only 80% to 85% of the CF mutations have been identified in most populations.[9]

If carrier screening for CF is offered to the general population, a primary interest group is likely to be pregnant women. A body of literature exists that describes and analyzes the attitudes and behavior of women toward screening and prenatal diagnosis in a variety of circumstances.[10–18] However, CF has its own distinctive features as a disease, including its morbidity and mortality, risk levels, and the population group at risk. This pilot study was undertaken to explore the interest in carrier screening for CF in pregnant women without a family history of CF and to determine the attitudes of such women toward the potential use of this information in making reproductive decisions.

Methods

Subjects were recruited from the obstetric clinics at a large urban county hospital in Cleveland and at a suburban health maintenance organization in northeastern Ohio. A consecutive sample of 306 pregnant Caucasian women at less than 18 weeks' gestation was recruited to participate in the study. The participants' baseline knowledge of CF was assessed by their responses to three questions; the women were then asked to read educational materials and complete a 40-item questionnaire at home. The participants were encouraged to complete the questionnaire with the father of the baby, when appropriate. Respondent confidentiality was maintained. Pretest responses were available from 84 women who did not return the questionnaire.

Part 1 of the questionnaire assessed demographic information, attitudes about the present pregnancy, and history of previous pregnancies. Part 2 of the questionnaire consisted of information about CF, the carrier state, and reproductive options for carriers. The information was written at a 10th-grade reading level. The information was reviewed for accuracy and balance by parents of persons with CF and by medical specialists. Part 3 of the questionnaire consisted of a test of factual knowledge about CF, followed by items designed to ascertain attitudes about testing and reproductive decisions. Most questions were designed to elicit yes or no responses on a 4-point scale: (1) Yes, definitely; (2) Yes, probably; (3) No, probably not; (4) No, definitely not.

Data were analyzed with the Statistical Package for the Social Sciences/PC+. Analysis for this project consisted primarily of univariate and bivariate analysis, including cross-tabulation and correlational procedures.

Results

Of the 306 questionnaires distributed, 214 were returned in usable form, for a

[b]No (Total) = "No, definitely not" + "No, probably not."

response rate of 70%. There were no variables with more than 2% missing data. The demographic characteristics of the study population (Table 1) demonstrate participation by women with a broad range of demographic and socioeconomic characteristics.

Seventy-eight percent of the respondents had heard of CF, and 14% of those had known someone with the disease, although none had siblings or children with CF. Of those who had heard of CF, 47% were aware that it was a disease of the lungs. There was no significant difference in baseline knowledge between responders and nonresponders (n = 84).

Responses to the knowledge questions (Table 2) demonstrate that the participants read the information and that the information was effective in transmitting factual knowledge of CF. It is notable that 11% of the women responded incorrectly that the risk of two carriers' producing an affected child is 100%. Respondents also were likely to underestimate their personal risk of being a carrier: 43% responded that they were at a 1 in 400 risk of being a carrier (the lowest risk level offered as a choice). For each of these two questions those answering incorrectly were less likely to have attained a high level of formal education than were those who answered correctly ($P \leq .01$).

The results shown in Table 3 demonstrate that the participants had a strong interest in being tested for CF carrier status before pregnancy (84%) and during pregnancy (69%). Those who had heard of CF ($P \leq .01$), those who knew someone with CF ($P \leq .01$), those who answered correctly on the nature of CF on the pretest ($P \leq .05$), and those who attended religious services frequently ($P \leq .01$) were *less* likely to want carrier testing during pregnancy. Age, education, and employment were not predictive of the desire to be tested, and those who underestimated their personal risk of carrier status were not less likely to want testing.

With respect to reproductive choices (Table 4), the majority of women (67%) said they would be interested in prenatal diagnosis if they were at risk for having a child with CF; however, a minority (29%) expressed a willingness to terminate a pregnancy if the fetus were found to have CF. Choices about abortion were not related to age, education, employment, pretest knowledge of CF, or perceived risk. Our sample contained a high proportion of Catholic women; however, Catholics were not less likely to choose abortion, nor were those who said they had a religious affiliation versus those who did not.

To estimate the proportion of affected pregnancies that would have been identified and terminated in our sample population, we analyzed the data to estimate the sample's use of testing for each stage of a screening protocol. These results (Table 5) suggest that approximately 24% of affected pregnancies among the women offered screening would have been identified and terminated as a result of a carrier screening program. This estimate assumes a 100% test sensitivity.

With respect to issues of confidentiality and free choice, 99% of the respondents indicated that they would be willing

to share their test results with family members. A large majority (80%) felt that carrier testing should not be required by law, and 60% said that physicians should not be required to divulge the results of CF testing to family members against the wishes of the patient.

Discussion

The results demonstrate a substantial interest in carrier screening in this sample and support a design for a program that is voluntary and confidential. Although the majority of the women were interested in knowing their carrier status, most indicated a reluctance to use the information to prevent the birth of an affected child. Of particular interest is our finding that those who were more familiar with CF tended to be less interested in carrier screening. The hypothetical nature of this study limits our ability to make confident predictions of actual behavior in a screening program, and attitudes may vary with time, clinical approach, and test validity. □

A Cohort Study of the Impact of Perinatal Drug Use on Prematurity in an Inner-City Population

Joseph G. Feldman, DrPH, Howard L. Minkoff, MD, Sandra McCalla, MD, and Martin Salwen, MD

ABSTRACT

Perinatal illicit drug use was determined by anonymously testing the urine of 1111 inner-city parturients. Fourteen percent tested positive, 11.5% for cocaine. As determined by self-report or by positive test results, 17% used drugs. Twenty-eight percent of low birthweights and 20% of premature births in this group were attributable to drug use. Risk of prematurity was reduced by a factor of 2 to 3 with adequate prenatal care. These data suggest an enormous potential for improving perinatal health. (*Am J Public Health.* 1992;82:726–728)

Introduction

Cocaine use has increased substantially among pregnant women over the past 10 years,[1,2] in association with adverse effects such as low birthweight, prematurity, and small head circumference.[3–6]

Most previous studies used small and selective samples.[3,6] We studied the urine of 1111 inner-city women who delivered over a 4½ month period, and found that cocaine metabolites in the urine of parturients were associated with decreased use of prenatal care services, higher parity, more sexually transmitted diseases, lower birthweight, and more preterm births.[7,8] In the present study, we estimate the impact of drug use on low birthweight and prematurity in an inner-city community.

Methods

Our study methods have been described previously.[7] Women delivering at a municipal hospital in New York City between October 18, 1988 and March 1, 1989 (1331 women) were eligible for participation. Entry criteria were admission and/or delivery on a shift staffed by study personnel. Specimens obtained from parturients for routine urinalysis were saved, refrigerated, given code numbers, and results combined with the other patient information.

Data collected included demographic information, history of drug use, and pregnancy outcome measures, which were available for 1111 patients. Study pediatricians assessed all newborns during several shifts per week but were not always available, and so the number of infants included in the study (846) was less than the number of mothers. Pediatric assessment included head circumference, length, and gestational age (judged on the basis of a physical examination).

Prenatal care was categorized as received at the delivering institution (YES); received at a different institution at least once during pregnancy (OTHER); no care reported (NONE).

Urine screening for illicit drugs was done on a Hitachi 705 analyzer with a homogeneous enzyme-multiplied immunoassay technique[9–10] (details available on request).

Statistical Methods

Determination of exposure to drugs, either by urine toxicology or by history, was made before pregnancy termination and without knowledge of the birth outcome.

Multiple logistic regression models were used to estimate the association of drug exposure to birth outcome, adjusting for other factors including cigarette use, alcohol use, hypertension, maternal age, parity, and use of prenatal care.[11]

The population attributable risk (AR), the proportion of prematurity in the community that was caused by the mothers' exposure to drugs during pregnancy, was estimated as follows[12]:

$$AR = \frac{(\%\text{ of drug use}) \times (\text{relative risk of outcome} - 1)}{1 + (\%\text{ of drug use}) \times (\text{relative risk of outcome} - 1)}$$

Relative risks were estimated from multiple logistic regression models, adjusting for the variables noted above.

Results

The 265 mothers for whom information about offspring was unavailable were

Joseph G. Feldman is with the Department of Preventive Medicine, Howard L. Minkoff and Sandra McCalla are with the Department of Obstetrics and Gynecology, and Martin Salwen is with the Department of Pathology, all at the State University of New York, Health Science Center at Brooklyn.

similar to the 846 for whom pediatric information was available with respect to drug use and demographic characteristics.

The average age was 25.6 ± 6.0 years. Ninety-one percent of the parturients were Black (two thirds were born in the United States), and 9% were of Hispanic origin. Median parity was two. About two thirds were unemployed. Of drug users, 11.5% used cocaine, 1.2% used marijuana, 1.3% used opiates, 0.4% used methadone, and 3.1% had negative urine tests but positive histories. Table 1 shows the regression coefficients, *P* values, and the odds ratios and their 95% confidence intervals for the variables included in the final model for predicting birthweight of less than 2500 g. Drug users were at 3.3 times greater risk of giving birth to a child weighing less than 2500 g, independent of other factors, such as age, parity, hypertension, alcohol, or prenatal care. Agreement was good between the observed and expected frequencies of low birthweight by deciles of risk, based on the model (Chi-square [8 *df*] = 7.58, *P* = .48). Table 2 shows the results for the logistic regression with premature birth as the outcome. The impact of the predictor variables was similar for both birthweight and premature birth. Statistically significant predictors in both models were hypertension, prenatal drug use, and absence of prenatal care.

Table 3 shows observed and predicted odds ratios for low birthweight and premature birth categories of drug use and prenatal care. There was good agreement between the observed and predicted odds ratios, again suggesting that the logistic regression models were representing the data adequately. Drug use and absence of prenatal care were each associated with a two- to threefold elevation in the risk of premature birth. Absence of prenatal care combined with drug use increased risk six- to ninefold.

Table 4 shows the actual percentages of low birthweight and premature birth for the categories of prenatal care and drug use.

Using the definition of attributable risk described earlier, and standardized odds ratios of 3.34:1 for low birthweight and 2.64:1 for premature birth in infants exposed, estimates of community attributable risk due to drug use were as follows:

$$\text{AR (low birthweight)} = \frac{.171 \times 2.24}{1 + (.171 \times 2.24)} = 27.7\%$$

TABLE 1—Multiple Logistic Regression Analysis of Outcome Birthweight Less than 2500 G

$$AR\ (prematurity) = \frac{.154 \times 1.64}{1 + (.154 \times 1.64)} = 20.2\%$$

Discussion

In an inner-city hospital, 17% of parturients had evidence of drug use during pregnancy, with cocaine accounting for 83% of positive toxicologies.

After adjustment for several factors such as hypertension, age, parity, and cigarettes, drug use was estimated to be responsible for between 20% and 30% of the premature births occurring in the parturients' community. Documented prenatal care was associated with a two- to threefold reduction in prematurity, even in drug users.

Prematurity is a preeminent public health problem in the United States,[13-14] and cocaine use during pregnancy has been associated with preterm births.[1,4,5,7,15] Although a physiologic basis for cocaine-derived preterm birth has been suggested,[16] some authors have not found an increase in population prematurity rates despite rapid increases in rates of cocaine use.[17] Our data support not merely an association between cocaine and preterm birth, but a substantive contribution of cocaine to prematurity within an inner-city community.

The relationship among cocaine use, the absence of prenatal care, and poor pregnancy outcomes[7,8] partly reflects the more desperate circumstances and more intense drug use of "unregistered" patients. Most drug users (70%) were also cigarette smokers, and cigarette smoking is known to cause prematurity. It is probable that some portion of the 20% to 30% risk of prematurity attributable to drug use in this study would remain if parturients persisted in smoking during pregnancy. Nonetheless, one third of low-birthweight births in the United States occur in populations similar to the one studied (poor and minority), suggesting that drug use, particularly use of cocaine, contributes substantially to national infant morbidity. □

The Impact of Mailing Psychoeducational Materials to Women with Abnormal Mammograms

Caryn Lerman, PhD, Eric Ross, ScM, Alice Boyce, MA, Pat McGovern Gorchov, MPH, Robert McLaughlin, Barbara Rimer, DrPH, and Paul Engstrom, MD

ABSTRACT

A randomized trial was conducted to evaluate the impact of mailed psychoeducational materials on adherence to subsequent annual mammography among women with prior abnormal mammograms. The results showed a 13% increment in adherence among women who received this intervention. This effect was independent of all sociodemographic and medical variables examined. We conclude that mailed psychoeducational materials may be an effective mechanism to improve adherence among women with abnormal mammogram results. (*Am J Public Health.* 1992;82:729–730)

Introduction

As use of mammography screening increases, an increasing number of women will have abnormal mammograms. The proportion of mammograms interpreted as abnormal in large screening programs is as high as 15% to 20%.[1,2] Thus, if 15% of the 48 million American women 40 years of age or older have mammograms, there would be more than 1 million abnormal mammograms per year.[3] Adherence to annual mammography screening is important for women with abnormal mammograms, because some of these women have an elevated risk for breast cancer.[4]

We conducted a randomized trial involving a mailed psychoeducational booklet to improve adherence to subsequent annual mammography among women with abnormal mammograms. The impact on adherence of two different styles of presenting educational information also was tested. On the basis of Prospect Theory,[5,6] we predicted that communications that emphasize the negative consequences of nonadherence (negative framing) would have a greater positive impact on adherence than equivalent communications that emphasize the positive consequences (positive framing).

Methods

Study Population

Respondents were 446 women, aged 50 to 74 years, who were members of the Health Maintenance Organization of Pennsylvania and New Jersey (HMO PA/NJ). Eligible respondents were those who had received an abnormal mammogram during the previous year and were eligible to receive an annual screening mammogram during the study period (March 1990 to May 1991). As part of their HMO membership, all respondents received an informational brochure and a referral for a free mammogram annually.

The study sample was selected from a pool of 936 women who met the above criteria. One hundred ninety-one women were excluded in the course of the study for the following reasons: discontinued HMO (10%), age ineligible (6%), cancer diagnosis (3%), and not eligible for mammogram (1%). Other women (n = 210) were excluded during the baseline survey phase because of unavailable telephone numbers (25%), refusals (3%), and language barriers (0.5%). An additional 89 women (17%) were lost during the follow-up survey phase for one of the above reasons. The final sample (n = 446) was not significantly different from the original sample in age, education, or mammogram results.

Procedures

Respondents were randomized into one of four study groups: (1) no survey—control, (2) survey—control, (3) survey—psychoeducational booklet/negative framing, and (4) survey—psychoeducational booklet/positive framing. The randomization was stratified by prior mammogram result (i.e., low suspicion/showing asymmetric breast tissue vs high suspicion/showing mass). Baseline telephone surveys of sociodemographic and medical characteristics were conducted with respondents randomized to groups 2, 3, and 4. Response rates across these three groups were not significantly different (overall rate = 71%).

One month later, intervention group respondents were mailed a 12-page psychoeducational booklet that described the meaning of abnormal mammograms and emphasized the necessity of continued screening. Suggestions for managing mammography-related anxiety also were included. Two versions of these printed

TABLE 1—Number and Percentage of Respondents Who Adhered to Mammography (n = 446)

Study Group[a]	Mammogram Result: Low Suspicion No.	Low Suspicion %	High Suspicion No.	High Suspicion %	All Results No.	All Results %
Control—no survey	49	49	31	60	80	53
Control—survey	32	59	18	49	50	55
Experimental—positive	40	71	22	59	62	66
Experimental—negative	46	65	27	69	73	67
All groups	167	59	98	59	265	59

[a]Study group effect significant ($\chi^2 = 7.76$, $P < .005$).

materials varied in terms of the "framing" of educational messages; however, the message content was equivalent.

One week later, all respondents were mailed the standard HMO breast screening packet, which included the free mammogram referral. Follow-up telephone calls were conducted with all respondents 3 months later, following expiration of the mammogram referrals, to assess adherence (response rate = 89%). Self-reported mammography adherence in this population has been shown to be highly reliable.[7]

Results

The average age of respondents was 60 years (SD = 6.8). The majority of women were White (85%) and married (71%). Eighty-two percent had at least a high school education. Sixty-three percent had a low-suspicion abnormal mammogram, and 37% had a high-suspicion abnormal mammogram. Fifteen percent had a biopsy after their abnormal mammogram; 16% received additional imaging (ultrasound or repeat mammogram) and 68% did not require diagnostic follow-up. There were no significant differences in these variables between study groups.

Overall, 53% of women in the two control conditions obtained their annual mammograms, compared with 66% of women who received the psychoeducational booklet ($\chi^2 = 7.76$, $P < .005$). Adherence rates in the two control groups were not different (53% vs 55%), suggesting that the baseline survey did not boost adherence. Adherence rates in the two intervention groups were not significantly different (66% vs 67%), suggesting that the framing of information had no effect.

Logistic regression analysis examined the effect of study group while controlling for the index of suspicion on the prior mammogram result and for sociodemographic variables. Study group (control vs booklet) was a significant independent predictor of subsequent mammography adherence (odds ratio = 1.7, $P < .005$). The interaction between study group and level of suspicion of the prior mammogram was not significant. No sociodemographic factor predicted adherence significantly.

Discussion

This randomized trial demonstrated a significant positive impact of a mailed psychoeducational booklet on mammography adherence among women with prior abnormal mammograms. The intervention groups demonstrated 13% greater adherence to subsequent annual mammography. Further analyses indicated that the framing of educational messages did not differentially affect adherence. Also, adherence was not associated with sociodemographic factors or prior mammogram result.

These results have implications for the management of women with abnormal mammograms. Our previous research has indicated that a substantial proportion of these women have psychological difficulties, even after learning that they do not have cancer.[1] Psychoeducational interventions tailored to the unique needs of these women potentially can ameliorate excessive distress and promote continued adherence.[8] Such communications should provide messages to heighten perceived vulnerability to breast cancer[9] but should be balanced with reassuring messages that emphasize the potential for early breast cancer detection and cure.[9–11]

This study was conducted in an HMO population. Women who elect to join an HMO may differ from the general population. However, our previous research suggests that members of HMO PA/NJ share the same sociodemographic backgrounds as nonmembers in the same geographic areas.[12] Future research is necessary to evaluate the impact of mailed educational materials in other populations with cost and access barriers. □

Breast-feeding Patterns in a Rural Village in Giza, Egypt

Iman A. Hakim, PhD, and Iman A. El-Ashmawy, PhD

ABSTRACT

In a longitudinal study of infant feeding in rural Giza, Egypt, we found that 68.8% of the recruited mothers initiated early suckling of colostrum, but only 51.2% of the infants were exclusively breast-fed in the first week. Solid foods were introduced much earlier than at the recommended age of 4 to 6 months. Sixty percent of the mothers who participated in the study considered breast-feeding plus regular or irregular complementary feeding to be exclusive breast-feeding. (*Am J Public Health.* 1992;82:731–732)

Introduction

A high rate of breast-feeding is beneficial for the developing countries with regard to both economy and health. It is well known that colostrum improves the infant's chances of survival by providing both nutrition and immunization, specific and nonspecific, during the neonatal period.[1] Early suckling is therefore important to the infant and also stimulates the production of mature milk.[2]

Several studies[3–5] that distinguish between exclusive and partial breast-feeding have shown that a high percentage of infants in the developing countries are exclusively breast-fed for very short periods. The early introduction of water and food in environments where contamination is common not only exposes infants to concentrated numbers of microorganisms that may overwhelm the immunological protection provided by breast milk,[6] but also reduces stimulation of the breast, causing a reduction in the milk supply.[7]

Consequently, the study of infant feeding patterns during the neonatal period and the exclusive and partial breast-feeding periods is of crucial importance for an understanding of how to improve breast-feeding practices in the developing countries.

Methods

Mothers whose infants were born in 1989 and who attended the maternal and child health clinic in El-Kata, a rural village in Giza, Egypt, were asked if they would participate in a 1-year study of their infants' feeding patterns. The selected clinic and village are representative of rural Giza. The mothers of 250 infants were recruited.

At registration, the mothers were asked to provide information about themselves and their families, including the mother's level of education (no school, elementary school or less, or more than elementary school).

The mothers were interviewed for 1 year at weekly intervals from the time their infants were about 1 week old. At each interview, the mothers were asked about their infants' feeding. The mothers' definitions of "exclusive breastfeeding" were recorded in their own words.

The obtained data have been divided into 12-month equal intervals, with special interest in the first week of neonatal feeding. The Data Base III Plus program was used for data analysis.

Results

Of the 250 women enrolled in the study, 176 (70.4%) had had no schooling, 10 (4%) had an elementary-school education or less, and 64 (25.6%) had more than an elementary-school education.

Early suckling of colostrum was initiated by 68.8% of the mothers. We found that 61.4% of the uneducated mothers and 84.4% of the educated mothers (those with more than an elementary-school education) initiated early suckling of colostrum (Table 1). Causes of delayed suckling were found to be as follows: insufficient milk, 48%; traditional habits, 34.7%; tired mother, 6.2%; cesarean section, 4.1%; sick mother, 3.8%; weak baby, 3.1%.

The percentage of infants who were actually exclusively breast-fed in the first week was only 51.2%. The rest of them were given sugary fluids, honey and butter, or milk formula, or were fed by another lactating woman in the family. We found that 47.2% of the uneducated mothers and 70.3% of the educated mothers practiced exclusive breast-feeding in the first week.

Our results revealed that 128 infants (51.2%) were exclusively breast-fed for 1 week, 125 (50%) for 2 months, 106 (42.4%) for 3 months, 97 (38.8%) for 4 months, 86 (34.4%) for 5 months, 72 (28.8%) for 6 months, and 46 (18.4%) for 7 months. None of the infants was exclusively breast-fed after the age of 7 months; instead, they were given any available food, either regularly or irregularly.

TABLE 1—Percentages of Women Who Initiated Breast-feeding in the First Week

Start of Breast Suckling	Total (n = 250) No. (%)	Mother's Education: No School (n = 176) No. (%)	≤ Elementary (n = 10) No. (%)	> Elementary (n = 64) No. (%)
Colostrum				
Immediately after birth	60 (24.0)	52 (29.6)	0 —	8 (12.5)
After a few hours	61 (24.4)	26 (14.8)	5 (50.0)	30 (46.9)
Second day	44 (17.6)	28 (15.9)	0 —	16 (25.0)
Third day	7 (2.8)	2 (1.1)	5 (50.0)	0 —
Transitional				
Fourth day	22 (8.8)	22 (12.5)	0 —	0 —
Fifth Day	38 (15.2)	38 (21.6)	0 —	0 —
Sixth day	5 (2.0)	5 (2.8)	0 —	0 —
Seventh day	13 (5.2)	3 (1.7)	0 —	10 (15.6)

Only 40% of the mothers defined exclusive breast-feeding as giving breast milk only; 60% considered exclusive breastfeeding to include complementary feeding (giving breast-milk in conjunction with other foods). Also, 93.3% of the educated mothers described exclusive breast-feeding as giving breast milk with regular supplementary feeding (substituting 1 or more breast-feedings with other foods regularly) (Table 2).

Discussion

Mothers are encouraged to breast-feed their infants, but sooner or later, other foods and milk must be given to the infants.[8] In many cultures, colostrum is withheld or given sparingly.[9] In our study, the majority of the rural women (68.8%) initiated suckling of colostrum within the first 3 days; the remaining 31.2% started breast-feeding later. Only 51.2% of the infants were exclusively breastfed. The rest were given mixtures of sugar and water, honey and butter, tea and biscuit, formula, or were fed by another lactating woman in the family. Such foods were given in conjunction with breast milk for about 1 week or until mature milk became available. This practice was followed mainly because colostrum was said to be insufficient for the infant's energy needs and also because of the traditional belief that breast milk is not available for the neonate before 3 days, during which the infant may be fed by another lactating woman.

Maternal education, health behavior awareness, and increased capacity to change health belief systems are strongly correlated with initiation of breast-feeding.[10] In the present study, educated mothers were more likely to initiate early breast-feeding than were uneducated mothers. Similarly, infants of educated mothers were more likely than those of uneducated mothers to be exclusively breast-fed in the first week.

We found that 48.8% of the infants received not only mixtures of sugar and water, milk formula, and solids soon after birth and for about 1 week thereafter, but also complementary foods now and then until this became a regular practice. Solid foods were introduced much earlier than at the recommended age of 4 to 6 months[11] in 51.6% of the infants studied, often (in 3.2% of the infants) in the first month of life.

Mothers were frequently advised to introduce complementary foods on the basis of presumed milk insufficiency as soon as a problem, no matter how trivial, came up.[12] This pattern could be defined as regular complementary feeding or partial breast-feeding. Sixty percent of the mothers, however, described such a feeding pattern as exclusive breast-feeding.

It is crucial that we be aware of the very low prevalence of exclusive breast-feeding and the widespread practice of very early and irregular complementary feeding in the developing countries. Breast-feeding should be encouraged, but it is also important that irregular complementary feeding during the early weeks of life be strongly discouraged, unless such feedings are medically indicated. It seems likely that a change in this very early feeding pattern would contribute to a significant decline in the prevalence of neonatal systemic infection in the developing countries. □

TABLE 2—Mothers' Definitions of Exclusive Breastfeeding

Definitions	Total (n = 250) No. (%)	Mother's Education: No School (n = 176) No. (%)	≤ Elementary (n = 10) No. (%)	> Elementary (n = 64) No. (%)
Breast milk (BM)	100 (40)	96 (54.6)	0 —	4 (6.2)
BM & sugary fluid	35 (14)	28 (15.9)	7 (70)	0 —
BM & tea and biscuit	20 (8)	17 (9.7)	3 (30)	0 —
BM & available foods	25 (10)	25 (14.2)	0 —	0 —
BM & regular monthly supplements	70 (28)	10 (5.6)	0 —	60 (93.8)

Access to Cancer Screening Services for Women

Bradford Kirkman-Liff, DrPH, and Jennie Jacobs Kronenfeld, PhD

ABSTRACT

A major effort in preventive care for women has emphasized the obtaining of Pap smears and mammograms. This paper uses survey data from one state to examine issues of access to Pap smears and mammograms. Poor women receiving health care through a managed-care Medicaid program received these services at the same rate as women with other types of health insurance, while the uninsured were less likely to have had either type of service. (*Am J Public Health.* 1992;82:733–735)

Introduction

One preventive care emphasis for women is obtaining Pap smears and mammograms to detect cancer at an earlier, more curable stage. Recent studies have particularly linked poverty to cancer risk.[1–3] This paper uses survey data to examine issues of access to Pap smears and mammograms. Of particular interest is whether poor women receiving health care through the Arizona Health Care Cost Containment System (AHCCCS), a unique, managed-care Medicaid program, receive these services at the same rate as women with other health insurance. Earlier studies reported that poverty, age, no health insurance, and no recent visit to an obstetrician/gynecologist related to lack of Pap tests and that poverty, low education, and age related to lack of mammograms.[3–9] This analysis compares AHCCCS women with uninsured women and women with other types of insurance. Unique to this analysis is the inclusion of use of each service (Pap smear, mammogram) in the model for the other service. Previous studies have generally focused on only one aspect of screening services.

Until 1981, Arizona had no Medicaid program. AHCCCS, a managed-care/health maintenance organization alternative to traditional fee-for-service Medicaid, was designed to provide cost-effective care that avoids excessive costs from overuse. The program operates through a network of capitated, managed-care plans with primary-care physicians as gatekeepers who coordinate all needed services. Plans competitively bid and negotiate for contracts and are at financial risk for overuse. Eligible recipients must obtain all care from their selected plan.

Methods

Survey data were collected in 1989. About 3100 randomly selected adults were interviewed about themselves, and 1100 about a randomly selected child. Interviews were conducted in English or Spanish. Further details on this survey have been published elsewhere.[10] Four measures of access to cancer screening services were examined. In addition to a dichotomous variable of whether a woman ever had a test, women who had been screened by each test were asked when it occurred. Women who had received each service were split into those receiving it within 2 years prior to the survey and those 3 years or more before the survey. We also examined whether women who had a Pap smear were more likely to have a mammogram, and vice versa. Mammogram analyses included only women over 40, since mammogram services are not recommended at regular intervals before age 40.[11]

In addition to examining the impact of insurance status and the AHCCCS program, other variables were hypothesized to affect use of preventive services. The different cultural values of Latino women may lead to different use patterns. (Numbers are too small to allow analyses of African-American and Native American women.) Latino women interviewed in Spanish were expected to have differences from those interviewed in English, with language of interview serving as an acculturation proxy. Educational attainment would affect receptivity to cancer screening messages, with less-educated women reporting lower use. Women with no usual health care source would have lower use of cancer screening services than women with a usual source. Women who needed health care but were unable to obtain it were expected to have lower Pap smear/mammogram use. Number of visits with health providers was expected to increase the likelihood of receiving cancer screening services, possibly nonlinearly. Lastly, age would have a varying effect, depending on the specific service.

Results

Overall, 68% of women had a Pap smear in the 2 years prior to the survey, 23% had a Pap smear 3 years or more prior to the study, and 9% never had a Pap smear. Exploratory cross tabulations showed statistically significant differences by insurance status, education, usual source of care, and needing but not receiving medical care (Table 1). Overall, 47% of women had a mammogram in the 2 years prior to the survey, 11% had a mammogram 3 years or more prior to the study, and 42% never had a mammogram. Only insurance status and usual source of care were significantly related to use of mammograms (Table 2).

Logistic regression was used to model the dichotomous measures. The results were transformed into odds ratios and 95% confidence levels. Variables without significant odds ratios are not presented, except for insurance. Women who had a mammogram were far more likely to have had a Pap smear than women without a mammogram, and women who had a Pap smear were far more likely to have had a mammogram than women without a Pap smear. Uninsured women and women with no usual source of care were far less likely to have had either service than women with conventional insurance, in AHCCCS, or with a usual source of care. Latino women were less likely to report a Pap smear, with no difference in mammograms (Table 3).

Women who had a mammogram were far more likely to have had a Pap smear within 2 years of the survey than women without a mammogram, and vice versa. Uninsured women and women with no usual source of care were far less likely to have had either service within 2 years of the survey than women with other insurance, AHCCCS, or a usual source of care (Table 4).

Discussion and Conclusion

Several important conclusions emerge from these analyses. The insignificant AHCCCS term indicates that a managed-care Medicaid-type model led to more appropriate use of preventive health services in cancer screening. AHCCCS women had no difference in access to these two preventive health services as compared with women with other insurance. Uninsured women and those with no usual source of care were less likely to have ever had the services or to have had them within the previous 2 years. In addition, older women and Latino women were less likely to have ever received a Pap smear. A recent editorial about race, poverty, and cancer concluded that poor Americans constitute a high-risk group for cancer.[12] This paper demonstrates that managed-care Medicaid programs can

help direct resources to people at higher risk. Some studies have emphasized the need for motivational programs to encourage usage.[4] In contrast, this study provides evidence that, without special motivational programs, if poor women receive health care services within a managed-care model with a preventive approach they have similar rates of use as the general population of insured women. □

Moderate Physical Activity and Bone Density among Perimenopausal Women

Jun Zhang, MB, Paul J. Feldblum, MSPH, and Judith A. Fortney, PhD

ABSTRACT

We examined the association between physical activity and bone mineral density (BMD) among 352 perimenopausal women. A personal activity computer was used to estimate the daily energy expenditure on physical activity. BMD was measured by photon absorptiometry at the lumbar spine, midradius, and distal radius. Multiple linear regression, controlling for other factors, indicated that physical activity was positively and significantly associated with BMD at all sites. Moderate physical activity has beneficial effects on BMD among perimenopausal women. (*Am J Public Health.* 1992;82:736–738)

Introduction

It has been suggested that exercise increases bone density[1] and prevents or decelerates age- and menopause-related bone loss.[2] Studies comparing highly trained athletes and sedentary individuals concluded that exercise increases bone density.[3–6] However, conflicting findings were reported from both cross-sectional and prospective studies with nonathlete subjects.[7,8] Block et al. suggested that inaccurate or subjective measurement of physical activity by questionnaires may, in part, account for the conflicting findings.[9] Small study sizes, resulting in low statistical power, may be another important factor.

The present study used personal activity computers to measure physical activity objectively. These devices are considered by some researchers to provide superior direct measurements of physical activity.[10,11] In addition to its large size, our study also adjusted for other determinants of bone density.

Materials and Methods

A group of 352 White women 40 to 54 years of age were recruited in central North Carolina by means of newspaper advertisement and flyers in workplaces, stores, and doctors' offices. Volunteers were required to have at least one ovary and no physical impairment inhibiting daily activities. Women who were pregnant, had smoked within the past 5 years, or were using estrogen replacement therapy were ineligible. Also excluded were women with a history of acromegaly, parathyroid disease, insulin-dependent diabetes mellitus, inflammatory bowel disease, liver disease (except hepatitis), or renal diseases (except pyelonephritis).

Participants completed a self-administered questionnaire that covered health history, reproductive and contraceptive histories, past and current exercise, and past and current diet. A simple life calendar was provided to aid recall. Menopausal status was defined on the basis of the combination of answers to items on menstrual changes, recent menses, and last menses. A woman was designated postmenopausal if she (1) reported menstrual changes, (2) reported no menstrual period in the previous 6 months, and (3) described herself as being in menopause. Others were designated premenopausal.

A series of questions concerning the respondents' exercise in high school were asked. Adolescent exercise was coded as follows: high level—played sports on a school team; moderate level—exercised regularly; and low level—did not exercise regularly.

A current food intake frequency chart was included in the questionnaire, from which dietary calcium was calculated.[12] We also queried the women about nondietary calcium in the form of antacids and dietary supplements. Based on the criterion of the recommended dietary allowance, subjects were dichotomized as above or below recommended total daily calcium intake.

Current physical activity was measured by a personal activity computer (Caltrac, Hemokinetics Inc, Madison, Wis), which is a portable accelerometer estimating daily energy expenditure in kilocalories.[11] The subjects were instructed to wear the device for 3 continuous days (all day long), including at least 1 weekend day and 1 weekday. Daily energy expenditure on physical activity was derived from total daily energy expenditure minus basal metabolic rate (BMR): BMR = [(331 × weight) + (351 × height) − (352 × age) + 49 854]/100 000 (kcal/min), where weight is measured in pounds, height in inches, and age in years.

*$P < .01$.
**$P < .001$.

Bone mineral density (BMD) was measured by dual photon absorptiometry at the second to fourth lumbar vertebrae, and single photon absorptiometry measured BMD at the midradius and the distal radius (5-mm site).

Results

The spine BMD slightly decreased with age, and postmenopausal women had substantially lower lumbar BMD than did premenopausal women (Table 1). Women who had ever breast-fed had significantly higher lumbar BMD than did nonbreast-feeding women. There was a modest dose–response relationship between exercise in high school and BMD at all sites that did not reach statistical significance. Women with more physical activity as measured by the personal activity computer had significantly higher bone density at the spine and distal radius. This association also prevailed at the midradius but was not statistically significant.

Multiple linear regression, controlling for age, body mass, breast-feeding, oral contraceptive use, exercise in high school, and menopausal status, indicated that current physical activity is directly and significantly associated with bone density at the spine, distal, and midradius sites (Table 2). Based on these coefficients, each additional 100 kcal/day energy expenditure in physical activity adds an estimated 12 mg/cm², 3.8 mg/cm², and 3.5 mg/cm² higher bone density at the spine, distal, and midradius sites, respectively.

Discussion

It has been established that highly trained athletes have significantly higher BMD than do sedentary persons.[3–6] Although research on this highly selected group suggests that intensive exercise increases BMD, the finding has lesser practical and public health value for perimenopausal women, for whom the issue of moderate physical activity may be of greater interest. The present study shows that perimenopausal women with more physical activity have significantly higher BMD when other determinants of BMD are taken into account.

Some limitations of our study should be noted. First, this was a cross-sectional study in which limited information on past exercise, body weight, and diet was collected. Second, misclassification may exist for some variables such as exercise in high school. Behavior change after adolescence may further lessen the value of this indicator. Third, although we improved the measurement of physical activity by using personal activity computers, it can be argued that 3 days of physical activity are not truly representative of the

TABLE 2—Multiple Linear Regression Analysis of the Association between Physical Activity and Bone Mineral Density

Site	Beta Coefficient[a]	SE	95% Confidence Interval	*P* Value
Spine L_2–L_4	0.1203	0.0386	0.0443–0.1963	.0021
Distal radius	0.0375	0.0161	0.0060–0.0691	.0207
Midradius	0.0350	0.0156	0.0040–0.0656	.0261

Note. L_2–L_4 = second to fourth lumbar vertebrae.
[a]Multiple linear regression analysis adjusted for age, Quetelet index, months of breast-feeding, months of oral contraceptive use, exercise in high school (ordinal), and menopausal status (dichotomous). Quetelet index = weight (lb) × 100/height (in)^2.

women's life-styles. Some women might have increased their exercise in the 3 measured days because of the study. Furthermore, since the device could only measure acceleration and deceleration in a vertical direction, some types of exercise, such as bicycling, may accumulate too few kilocalories. If this were true, however, the bias would be in the direction of the null because of increased variance. Thus, our significant findings suggest either that there is no strong bias in the physical activity results in our study or that the relationship between activity and BMD was underestimated.

Nonetheless, the advantages of the present study are noteworthy. The study size was substantially larger than most previous studies of exercise and BMD. Use of personal activity computers provided both objectivity and precision. In addition, the present study measured and adjusted for factors that were often overlooked in previous studies, such as breast-feeding, oral contraceptive use, and calcium intake. These advantages, along with the significant findings of this study and their biological plausibility and consistency with previous studies, lead us to conclude that moderate physical activity is associated with higher bone density among perimenopausal women. □

Medical Expenditures for Disability and Disabling Comorbidity

Dorothy P. Rice, ScD (Hon.), and Mitchell P. LaPlante, PhD

ABSTRACT

Disability and disabling comorbidity place a disproportionately large burden on the health care system. National Medical Care Utilization and Expenditure Survey data show that medical care expenditures for noninstitutionalized persons amounted to $154 billion ($691 per capita) in 1980. The medical expenditure per capita for people reporting two or more disabling chronic conditions ($2456) was 5 times the amount incurred by those with no limiting conditions ($486) and more than 1.5 times the amount incurred by those with one limiting condition ($1620). (*Am J Public Health.* 1992;82:739–741)

Introduction

Comorbidity, defined as the coexistence of multiple diseases and chronic conditions, has long been recognized as an important contributing factor in death.[1,2] The negative impact of comorbidity on health and functional ability has not been well documented until recently. A body of research is now emerging that focuses on the prevalence of comorbidity and its health consequences in representative samples of the population.[3–8] Data from the National Health Interview Survey show that disability and disabling comorbidity have increased recently. From 1970 to 1980, larger proportions of people were disabled by chronic conditions that limited their activities, and such persons reported more activity-limiting conditions per capita.[9]

Disability and disabling comorbidity place a large burden on the health care system, but the magnitude of the medical care costs involved has not been measured. This paper estimates the total and per capita medical expenditures in 1980 by number of activity-limiting chronic conditions and by age and type of expenditure.

Methods

The data on medical expenditures described here are taken from the 1980 National Medical Care Utilization and Expenditure Survey (NMCUES) conducted by the National Center for Health Statistics. A national probability sample of about 6000 households was augmented by samples drawn from the Medicaid eligibility rolls of California, Michigan, New York, and Texas (1000 households in each state). Data collection consisted of initial interviews during February through April 1980 and four rounds of follow-up interviews at approximately 3-month intervals.[10]

Information was collected on a wide range of topics related to health status, access to and use of medical services, associated charges, sources of payment, and health insurance coverage. This paper presents data obtained from the NMCUES public use data files, which contain only respondent data from the National Household Survey. Total charges were obtained for medical services and supplies in the survey. Missing information for critical data was imputed. Total charges for medical visits, hospital stays, and prescribed medicines and other medical expenses were imputed for 25.9%, 36.3%, and 19.4% of the events, respectively.[11] The methods used to impute for missing items were diverse and tailored to the measure requiring information.

Data are reported here on medical expenditures for persons with one and two or more limiting chronic conditions as assessed in Round 1. The number of persons reporting more than two conditions was not large enough to permit reliable estimates. A chronic condition is defined as having an actual or expected duration of more than 3 months. To be classified as limited, a person must report one or more chronic conditions as a cause of limitation of activity defined in terms of the major activities usually associated with a person's age group: (1) ordinary play for children under 5 years of age, (2) attending school for those 5 through 17 years of age, and (3) working or keeping house for persons aged 18 and over. Questions on functional limitations were asked only in the last interview (Round 5) and were not used in this analysis, although we recognize the utility of such measures, especially for older persons.[12]

Results

Of the 223 million noninstitutionalized persons in 1980, 36 million, or 16.2%, reported limitation of activity due to chronic conditions. About 85% (30.5 million persons) of those reporting activity limitations had one condition and the remaining 15% (5.5 million persons) had two or more conditions (Table 1).

Source: 1980 National Medical Care Utilization and Expenditure Survey. Authors' original tabulations from public use tapes.

Total expenditures for medical care for all noninstitutionalized persons amounted to $153.9 billion, or $691 per person, in 1980. The 187 million people with no activity limitations incurred $90.9 billion, or $486 per capita. Thus, 84% of those who reported no limitations incurred 59% of the total medical expenditures. By contrast, 14% of the people with one limiting condition incurred 32% of the total expenditures, while the less than 3% of those reporting two or more conditions incurred almost 9% of the total expenditures. On a per capita basis, expenditures for persons with one condition amounted to $1620, over three times the amount spent per capita for persons with no activity limitations. For those reporting two or more conditions, the medical expenditure per capita was $2456, 5 times the amount incurred by those with no limiting conditions ($486) and more than 1.5 times the amount incurred by those with one limiting condition ($1620).

Costs by Age

Total per capita expenditures increased fivefold with age, rising from $319 for those under age 19 to $1650 for the elderly aged 65 and over. More than 11% of the population were aged 65 and over in 1980, and this group incurred 27% of medical expenditures. Persons under 19 years of age constituted 31% of the population but accounted for only 14% of the charges.

This pattern of higher per capita charges for older persons also applies to those limited in activity because of one or more chronic conditions. For those reporting one condition, per capita charges rose from $734 for the youngest age group (under 19 years) to $2144 for the elderly. For those reporting two or more conditions, per capita expenditures rose from $1637 for those aged 19 through 44 to $3290 for those aged 65 and over. (There were too few cases under age 19 who reported two or more chronic conditions to produce reliable per capita charges.)

Comorbidity is often perceived as a problem associated with the aged population. Comorbidity rates among the noninstitutionalized population under age 65 were lower than for the elderly (1.7% and 9.0%, respectively, reported limitation of activity due to multiple chronic conditions). Nevertheless, the economic burden of comorbidity for the under-65 age group is substantial. Of the $37.8 billion in total medical expenditures generated by persons under age 65 reporting one or more limiting conditions, $6.2 billion, or 16.5%, was spent in behalf of persons reporting two or more conditions. For the elderly, $7.4 billion of the $25.2 billion, or 29.4%, involved those with two or more limiting conditions. Thus, those under age 65 generate 45.6% of the $13.6 billion of total medical costs for disabling comorbidity.

Type of Expenditure

Of the total medical expenditures amounting to $153.9 billion in 1980, almost one half (47%) involved hospital inpatient care and about 10% involved physician inpatient services. Outpatient services accounted for more than 20% of the total expenditures: $11.3 billion (7%) for hospital outpatient services and $20.6 billion (13%) for physician services provided outside the hospital. Charges for dental and other professional services amounted to $23.3 billion, 15% of total medical expenditures; charges for prescription drugs amounted to $7.8 billion (5%); and $3.7 billion (2%) was spent for other medical expenses (Table 2).

For each type of expenditure except for dental services, per capita charges for those with no limiting conditions were significantly lower than for persons reporting one or more limiting condition. For example, per capita charges for inpatient care for persons with one condition were five times the amount spent for those without limitations. For persons with two or more conditions, per capita hospital inpatient charges were eight times the amount spent for those without limitations. More than three fifths of the costs of comorbidity were due to inpatient hospitalization. It is clear that the existence of comorbid conditions results in longer hospital stays and higher overall costs.

Conclusions

This analysis clearly shows that medical care costs for disability and disabling comorbidity impose a large burden on society. The estimates presented here quantify only one portion of the economic and social costs. In addition to medical resources used, disability also results in reduced or lost productivity (estimated at $68.4 billion in 1980[13]), premature death, and pain and suffering of persons with disabilities, their families, and their friends. Considerable savings to society can be gained if the incidence and prevalence of disability and disabling comorbidity can be prevented or reduced. Comorbidity among people with disabilities can be prevented given appropriate access to care and health promotion.[14] The 1990 Americans with Disabilities Act was designed to improve access to jobs, transportation, housing, entertainment,

Swimming-Associated Cryptosporidiosis

Frank J. Sorvillo, MPH, Kenn Fujioka, PhD, Bernard Nahlen, MD, Michael P. Tormey, MPH, Richard Kebabjian, RS, and Laurene Mascola, MD, MPH

ABSTRACT

In July and August 1988, an outbreak of gastroenteritis affected 44 of 60 (73%) persons from 5 separate swimming groups who had used the same swimming pool in Los Angeles. *Cryptosporidium* was identified in 5 of 8 (63%) stool specimens, and the clinical picture was consistent with *Cryptosporidium* infection. Resistance of *Cryptosporidium* to chlorine, an inadequately maintained pool filtration system, repeated exposure to pool water, and possible continuing pool contamination may have contributed to ongoing transmission. *Cryptosporidium* should be considered a potential etiologic agent of gastroenteritis associated with recreational water use. (*Am J Public Health.* 1992;82:742–744)

Introduction

Since 1985, *Cryptosporidium* has been increasingly recognized as an important cause of gastroenteritis.[1] Outbreaks of cryptosporidiosis have been reported among day-care center attendees,[2] among travelers,[3,4] and in communities with contaminated water supplies.[5,6] Although outbreaks of enteric infection associated with recreational water contact have been documented,[7–10] however, swimming pool–associated cryptosporidiosis has not been previously reported.

In July and August 1988, an outbreak of diarrheal illness affected members of five separate groups of swimmers using the same private pool (Pool A) in Los Angeles County. The outbreak began within 1 week after a fecal accident in the pool in early July. The five groups, who had repeated pool contact during July, were a high school water polo team, a beginning scuba class, a masters swim group, elementary school students, and the lifeguard staff. The outbreak was not reported to health authorities until early August, when an investigation was initiated.

Methods

A standardized questionnaire was used to obtain information on the basic demographics of the persons involved in the outbreak and on clinical manifestations of and exposure to potential risk factors, including contact with day-care centers, travel outside the United States, consumption of untreated surface water, animal contact, common sources of food or water, and length and type of pool contact. To assess potential risk factors, the questionnaire was administered to a cohort of 32 elementary school students who had used two local pools; 16 who had used Pool A and 16 who had used another pool, Pool B. (Three students with exposure to both pools were not included in the analysis.) In addition, a case-control study was conducted among the remaining four groups. Thirty-six ill swimmers for whom family controls were available were compared with 72 unmatched, well family members. A suspect case was defined as any swimming group member, household contact of a group member, or school classmate with watery diarrhea or diarrhea plus cramping and/or fever from July 1 through August 31. Patients whose stool tested positive for *Cryptosporidium* were considered confirmed cases.

Data from an active surveillance system were reviewed to determine whether there had been a communitywide increase of gastrointestinal illness during July and August.

Laboratory results were obtained from physicians and/or laboratories where stool specimens were examined. Additional specimens were obtained from persons who continued to be ill. Samples were assessed for bacterial (*Salmonella, Shigella, Campylobacter*) and protozoan pathogens by standard methods. Stool specimens, which had been preserved, were obtained from private laboratories and evaluated for *Cryptosporidium* by the Los Angeles County Public Health Laboratories. Auramine O stain was used as an initial screen for *Cryptosporidium*, and a modified acid-fast stain was used as a confirmatory test. Viral studies were not performed.

An assessment of pool maintenance was made; however, attempts to recover *Cryptosporidium* from water were not made because the delay in investigation diminished the likelihood of recovering oocysts.

Chi-square, the Fisher Exact Test, a chi-square test for trend, and the *t* test were used to evaluate association of possible risk factors with illness. Relative risk (RR), odds ratios (ORs), and 95% confidence intervals (CIs) were calculated where appropriate.

Results

Interviews were completed for 60 of the 78 swimming group members (77%). Between July 13 and August 14, 1988, 44 group members developed gastrointestinal illness (Figure 1). The overall attack rate was 73% (44/60) and ranged from 47% to 100% by group. The median age of patients was 17 years (range 5 to 57) (Table 1); the male:female ratio was 1.2:1. Illness was characterized by watery diarrhea (88%), abdominal cramping (86%), and fever (60%), and it was often protracted (median duration 5 days). Thirty-two percent (14/44) sought physician consultation; two patients, both from the scuba class, were hospitalized.

Among the cohort of 32 elementary school students, illness was significantly more common among the 16 using Pool A (Fisher's Exact Test, $P < .01$, RR = 8, 95% CI = 1.1, 56.8). Differences in age or gender between those with and without exposure to Pool A were not noted.

For the remaining four groups, cases (35/36) were more likely than family controls (1/72) to have a history of exposure at Pool A during the outbreak period ($P < .001$, OR = 2485, 95% CI 125,22026).

The attack rate was highest for those having heavy (more than 3 total hours) water exposure (chi-square test for trend, $P < .001$) (Table 2). Cases with fever reported twice the extent of water contact than those without fever (mean hours 23.1 and 12.2, respectively, t test $P = .09$). No other common exposures or risk factors could be identified.

Cryptosporidium was identified in stool specimens from five of eight (63%) patients tested; no other bacterial or parasitic enteric pathogens were found. Stool samples from two control patients were negative for *Cryptosporidium*.

No increase in reported diarrheal illness during July and August in the county or the community affected by the outbreak was observed. Inspection of the pool during the outbreak period revealed adequate chlorine levels (2 ppm). However, one of three diatomaceous earth filters was inoperative, and the total filtration flow rate was 30% below the 230 gallons per minute recommended.

Discussion

Several factors support the conclusion that this was a swimming pool–related outbreak of cryptosporidiosis. The epidemic curve is consistent with a continuing common source outbreak. The observed association between exposure to Pool A and illness, the increasing attack rate and severity of disease with increasing water exposure, and the temporal occurrence of the outbreak following the fecal accident implicate the pool as the most likely source of infection. Identification of *Cryptosporidium* in affected patients and the absence of other parasitic or bacterial enteric pathogens indicate that *Cryptosporidium* was the etiologic agent in this outbreak. The clinical manifestations, together with the protracted nature of the illness, are also consistent with *Cryptosporidium* infections. It is unlikely that *Cryptosporidium* was an incidental finding, given that asymptomatic infection is rare.[11] The organism is infrequently found in stool samples during nonepidemic situations.[12] *Cryptosporidium* was not a reportable disease at the time of this outbreak. Therefore, the background prevalence of *Cryptosporidium* among immunocompetent persons in Los Angeles County was unknown. In addition, the level of chlorination (2 ppm) found during inspection of the pool was sufficient to inactivate other known enteric pathogens.

Resistance of *Cryptosporidium* to chlorination,[13] an inadequately maintained filtration system, repeated and often prolonged exposure, and the apparent low infectious dose of *Cryptosporidium*[14] may have contributed to ongoing transmission in this outbreak. Continued pool use and possible ongoing contamination of the pool by infected persons, many of whom continued to swim despite their illness, also could have helped sustain transmission. The increased attack rate observed for longer water contact may be related to a greater inoculum associated with swallowed water. The scuba class, which presented a high likelihood of swallowing large quantities of water, had the highest attack rate (100%), and the only patients hospitalized were from this group. The elementary school children, who might also be expected to swallow water, had much less water exposure than the scuba group. Because attempts to recover *Cryptosporidium* from the pool water were not made and patients were not tested for viral pathogens, our findings must be interpreted with caution.

Outbreaks of *Giardia intestinalis* infection and adenovirus types 4 and 3 associated with inadequately maintained swimming pools have been reported.[8,15–17] A well-maintained, fine-grade diatomaceous earth filtration system is probably effective in removing the small *Cryptosporidium* (4–6) oocysts.[18] Whether the commonly used rapid sand filters are able to remove oocysts is unknown.

Because chlorine is ineffective against *Cryptosporidium*, closure of a pool until relatively complete filtration has occurred should be considered as an additional measure for pool disinfection following fecal contamination for pools with diatomaceous earth filtration systems. Complete draining of the pool and cleaning of filter media may be necessary for pools with rapid sand filters. Although this outbreak followed a fecal accident, reliable information on the person who defecated in the pool was unavailable, and testing was not possible. Therefore, the causal role of the fecal accident in the occurrence of the outbreak is only suggestive.

Swimming-related cryptosporidiosis may be more common than previously recognized.[19] Public health authorities should have a high index of suspicion for *Cryptosporidium* as a possible etiologic agent during outbreaks of gastroenteritis associated with recreational water contact.

Although typically a self-limited infection in the immunocompetent host,[1] *Cryptosporidium* infection, for which there is no known effective therapy, may cause an unremitting diarrhea with significant morbidity and mortality in the immunocompromised patient.[20] There are an estimated 15 000 public swimming pools and 500 000 in-ground private pools in Los Angeles County. This is also an area of relatively high AIDS incidence and HIV seroprevalence.[21] The convergence of these factors creates the potential for swimming-related exposure of *Cryptosporidium* among highly susceptible persons at high risk of potentially life-threatening illness. □

Newspapers: A Source for Injury Surveillance?

David Y. Rainey, MD, MPH, and Carol W. Runyan, MPH, PhD

ABSTRACT

Newspapers have not been extensively evaluated as an injury surveillance source. We compared clippings with medical examiner records for 45 residential fire deaths and 58 drownings of children to assess extent, completeness, and accuracy of newspaper coverage. Newspapers covered 96% of the fire fatalities and 78% of the drownings and contained more information than medical examiner records on several factors, including fire cause and smoke detector presence, pool fences, warning signs, and supervision of children. (*Am J Public Health.* 1992;82:745–746)

Introduction

Public health surveillance is essential for injury control. Useful data include time, place, person, injury type, causation, circumstances, medical care, and health outcomes.[1] Death certificates and medical examiner records are routinely used for mortality surveillance but may not provide sufficient information about prevention. Newspapers are an available, inexpensive source of potential information.[2,3]

This study evaluated the extent, completeness, and accuracy of coverage provided by North Carolina newspapers of childhood fatalities from fires and drownings over a 13-month period.

Methods

By state law, all fatal injuries must be investigated by a local medical examiner and the reports filed with the North Carolina Office of the Chief Medical Examiner (NCOCME). Each file contains the death certificate, a narrative report describing the event, and, sometimes, reports of autopsy, police, and toxicology investigations.

All fatalities from residential fires and drownings among persons less than 19 years of age were identified through the NCOCME for the period January 1, 1988, through January 31, 1989.

Newspaper clippings reporting injury events during the study period were obtained from a commercial clipping service collecting all 72 daily and 186 nondaily newspapers published in North Carolina. When reports were not available from the clipping service, clippings were obtained from the University of North Carolina's newspaper library, medical examiner files, and local newspapers.

All fatal fires during the 13-month period were evaluated by interviewing local fire chiefs. The variables considered are listed in Table 1.

Newspaper clippings and medical examiner reports were matched and compared for the frequency of recording of the index variables. If a variable was reported as unknown or under investigation, it was listed as "not mentioned." The unit of analysis was the decedent, even if there was more than one death per fire or drowning event. When more than one clipping was found, the combined information was used. The accuracy of newspaper reports was measured by comparing newspaper coverage and (1) the fire chief interview and the NCOCME report (for fires) and (2) the NCOCME report (for drownings).

Results

Extent of Newspaper Coverage

The NCOCME reported 45 residential fire fatalities of children under age 19 during the 13 months. Twenty-two children died in fires that claimed more than one life. The clipping service retrieved reports on 39 of the 45 children. An additional four reports were found in the university library collection, for a total of 95.6% (43/45) coverage.

The NCOCME identified 58 drownings of individuals less than 19 years of age. Seven children died in drowning incidents that claimed more than one life. The clipping service produced 42 reports of the 58 incidents. An additional 3 reports were found in the library, for a total coverage of 77.6%. No deaths were identified by the newspapers for which an NCOCME report was not available.

Completeness of Newspaper Reports

Table 1 shows that, for 43 fires and 45 drownings, some information was not well covered by either source, but the newspapers were decidedly more complete with respect to a number of the variables studied. Most notably, clippings were more likely to include information about the

This work was conducted while David Y. Rainey was at the University of North Carolina Department of Maternal and Child Health and Preventive Medicine Residency Program, and Carol W. Runyan with the Department of Health Behavior and Health Education and Injury Prevention Research Center, University of North Carolina, Chapel Hill. David Y. Rainey is now with the Department of Pediatrics, University of Colorado.

cause of the fire or presence of a smoke detector than was the NCOCME report. However, medical examiner reports were much more likely to include the cause of death, alcohol use by the decedent, and race. Race was never reported directly in the newspaper but could be inferred from photographs in 15% of cases.

Findings were similar for drownings. The NCOCME report was more complete on race of the decedent, alcohol involvement, purported swimming ability, and resuscitation attempts. However, newspapers included more information about child supervision and characteristics of the body of water (public ownership, warning signs, and fencing).

Accuracy of Newspaper Reports

Newspapers and the fire chief interview agreed completely on age, sex, and race of the decedents and type of construction materials, but agreement was only 90.6% (39/43) for cause of the fire. The four disagreements resulted from the newspaper reporting a specific cause while the fire chief stated that the cause was unknown. Newspapers and medical examiner reports agreed completely on age, sex, and race of the decedent and type of water body.

Discussion

This study suggests that newspapers may be a useful adjunct to other injury surveillance efforts. Newspapers were more complete than NCOCME reports in supplying information about the cause and circumstances of fires and presence of protective factors for both fires and drownings. On the other hand, newspapers were not good sources of information about race or the possible involvement of alcohol. Otherwise, newspapers were accurate in reporting demographic information and causes and circumstances of fires.

Two issues are of particular interest. First, our results demonstrate that for childhood fire deaths and drownings, newspapers reported 96% and 78% of the cases, respectively. However, we located these articles knowing from the NCOCME that a death had occurred. To be optimally useful for surveillance, newspapers should be able to identify cases independently. Relying only on the clipping service would have resulted in reports of 91% of the fire deaths and 72% of the drownings.

Second, this analysis revealed that there is information about protective factors that is more likely to appear in the newspaper than in official records. This finding supports the value of newspapers and signals an area in which the medical examiner system might improve documentation. In fact, items to indicate the use of life preservers, swimming ability, and the presence of smoke detectors recently have been added to the NCOCME reporting form.

Besides surveillance, the reporting of injury events has potential value in raising public awareness about injury risks and protective measures. Newspapers should be encouraged to cover injury events fully and provide detailed information about protective measures. Injury surveillance efforts should consider newspapers as a potential source of valuable supplementary information, while still focusing on improving other systems of record keeping.

This study did not attempt to assess the specific methods or costs of the clipping service per se, factors that may vary by setting. Further research could document whether these findings generalize to other less dramatic or newsworthy injury problems and whether there are systematic differences in reporting policies or practices by publisher or locale. □

TABLE 1—Completeness of Coverage in Medical Examiner Reports and Newspapers: Child Fatalities in Residential Fires (n = 43) and Drownings (n = 45), North Carolina

	Medical Examiner (times reported, %)	Newspaper (times recorded, %)
Fires		
Age	100.0	100.0
Sex	100.0	100.0
Race	100.0	16.3

Response Comparability of Family and Staff Proxies for Nursing Home Residents

Sharon L. Tennstedt, PhD, Katherine M. Skinner, PhD, Lisa M. Sullivan, PhD, and John B. McKinlay, PhD

ABSTRACT

Response comparability on a wide variety of factual and judgmental information regarding nursing home residents was assessed for two proxy groups: family and staff. Family proxies had the most information. Family and staff proxies are not interchangeable. A general lack of response comparability suggests that proxies for nursing home residents should be selected in relation to the type of data needed and the time period of interest. (*Am J Public Health.* 1992;82:747–749)

Introduction

Because of the high prevalence of impairments among nursing home residents, proxy respondents are frequently required. Most studies of proxy response comparability have examined agreement between subject and proxy on factual information such as occupation, diet, smoking, and other disease risk factors,[1-3] although some have also examined agreement on items requiring judgment of health and functional status.[4,5] Much of this work has not been done on older populations, however; nor has it included nursing home residents. Further, most studies have not investigated the response comparability of two proxies of differing relationships—e.g., staff or family—to the elder subject. To examine the question of *who* is the best proxy respondent in studies of nursing home residents, this study (1) investigated proxy-proxy agreement on items involving both fact and judgment, and (2) examined the extent to which the subject-proxy relationship affected the extent and type of knowledge about the subject.

Methods

This study was part of a longitudinal study of the functional status and receipt of care of a geographically stratified sample of 4774 adults aged 70 or older, randomly selected from local census lists in Massachusetts. At first follow-up in 1989, the first 47 respondents who were determined to be alive and were admitted to a nursing home since the baseline survey 4 years earlier were identified for this study. Using the same instrument, interviews were conducted with these nursing home residents and two different proxies—i.e., a staff member familiar with the patient, as selected by the facility, and a family member, usually the preadmission caregiver. Order of interviews was assigned randomly. Resident and staff interviews were conducted in person at the same visit. Family interviews were conducted by telephone to contain costs.

Data regarding the resident included sociodemographics, date and reason for admission, preadmission use of formal services, preadmission and current receipt of informal care, and functional limitations. The Short Portable Mental Status Questionnaire (SPMSQ)[6] was administered to the resident to assess cognitive status. Additional data collected from the two proxy groups included frequency of current contact with the resident and current provision of care; knowledge of the resident's functional abilities; and, for family proxies, preadmission residential and caregiving status in relation to the resident. Judgment about the resident's functional limitations was reached through five questions designed to classify nursing home patients functionally.[7] These questions, their coding, and the summary statistics are provided in Table 1.

The percent agreement and Cohen's kappa (κ) statistic were calculated for categorical information provided by both proxies. Ranging from less than 0 to 1, κ values greater than 0.75 indicate excellent agreement and κ values less than 0.40 indicate poor agreement.[8] To test the significance of the κ statistic (i.e., the level of agreement that is more than expected by chance), z scores were computed from the observed κ statistics and their standard errors. One-tailed significance levels to detect more, rather than less, agreement by chance were also computed.

Results

Sample Description

The nursing home residents were predominantly female (70.2%), not married (91.5%), and very old (68.1% older

TABLE 1—Judgment of Functional Limitations

Question	Coding	Family Proxies		Staff Proxies	
		Mean	SD	Mean	SD
Does (resident) have any problem walking?	1. is independent 2. uses equipment and/or device 3. needs assistance 4. needs assistance *and* equipment/device 5. does not ambulate	2.87	1.71	2.85	1.56
Does (resident) have any problem dressing?	1. is independent 2. uses equipment and/or device 3. needs supervision 4. needs assistance 5. is totally dependent	3.72	2.01	3.70	1.38
Does (resident) need help with eating?	1. is independent 2. uses adaptive utensils 3. needs supervision 4. needs assistance 5. must be fed; needs tube/ parenteral feedings	2.51	2.04	2.23	1.40
Does (resident) have any bladder accidents?	1. is continent 2. uses catheter or ileal loop—self care 3. is incontinent <3x/wk 4. is incontinent ≥3x/wk 5. needs catheter or ileal loop—staff care	3.36	2.38	2.66	1.70
Does (resident) have any problem getting to or using the toilet?	1. is independent 2. needs supervision 3. needs assistance getting to/from toilet 4. needs assistance in use of bedpan/toilet 5. is totally dependent	3.04	2.47	2.70	1.90

than 85 years). The vast majority (82.5%) were scored as having moderate cognitive impairment on the SPMSQ (i.e., a score of 5 or more, adjusted for education) and were unable to complete the interview. Most (74.5%) had been admitted in the previous 2 years.

Most of the family proxies were offspring (63.8%), usually daughters, followed by other relatives (31.9%) and nonkin guardians (4.3%). Although only 31.9% had lived with the resident prior to admission, 78.7% had provided informal care. Staff proxies were social workers (72.3%) or nurses (27.7%). Frequency of contact was greater for staff, but 57.4% of family proxies saw the resident at least several times a week. Self-rated knowledge of the resident was equally good for both proxy groups.

Response Comparability

There was good to excellent agreement between the two proxies on the resident's sociodemographic characteristics (see Table 2). Agreement declined for questions related to the preadmission period. Although there was good agreement on who provided informal care, agreement was not good on types of informal care and formal services used. Staff proxies responded "don't know" more frequently than family proxies. Similarly, there was good agreement on who was currently involved with the resident but not on what the proxy did, except for providing transportation. There was generally poor agreement on most questions relating to major health problems except for diabetes, cancer, and heart conditions. Finally, there was slightly better agreement on items regarding functional limitations. Surprisingly, the area of least agreement was the ability of residents to feed themselves.

Discussion

The high prevalence of cognitive impairment in this sample of nursing home residents clearly suggests a need for proxy respondents in surveys of such populations. However, because most of the sample had moderate to severe cognitive impairment, it was not possible to ascertain response comparability between each of the proxies and the resident subjects themselves. Yet this study advances our knowledge by examining response comparability on general survey items involving both facts and judgment as well as between two different sources of proxy information.

It appears that family members have sufficient knowledge about the resident's current status and know more about the resident's preadmission data to be informed proxies. However, while item nonresponse for family member proxies is lower than it is for staff proxies, it is not possible to validate family proxy responses without self-report or medical record data. Such responses provide more information, but their accuracy requires further investigation. Despite this limitation, these findings have implications for study methodology.

The data suggest that proxies should be selected in relation to both the type of data needed and the time period of interest. Further, proxy selection may have to be item specific, and more than one proxy may be required to gather complete data.

An area requiring further study involves judgment of functional status. Other studies[4,5] have reported that proxies underestimate functional abilities when compared with elders' self-reports. This study showed lack of agreement between the two proxies. Perhaps there is no substitute for clinical observation of functional behaviors when collecting this type of data.

Finally, there is the possibility that the differing mode of administration (tele-

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 Fifteenth St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health,* 1015 Fifteenth St., NW, Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication and are not under consideration elsewhere.

Subscription price, individual, is $80/year US, $120/year international; **institutional,** $160/year US, $240/year international. Single copies $10 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 Fifteenth St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters.

Advertising Sales: Mary Beth Schultz, Advertising Manager, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. For cost information on 100 or more reprints, contact: Marilyn Butler, AJPH Reprints, APHA, 1015 Fifteenth St., NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols. 1 to present are also available on microfilm.

Use of Community-Based Mental Health Programs by HMOs: Evidence from a Medicaid Demonstration

Jon B. Christianson, PhD, Nicole Lurie, MD, MSPH, Michael Finch, PhD, Ira S. Moscovice, PhD, and David Hartley, MHA

ABSTRACT

Background. Proposals to enroll Medicaid beneficiaries in health maintenance organizations (HMOs) have raised concerns that community-based mental health treatment programs would be adversely affected.

Methods. In Hennepin County (Minnesota) 35% of Medicaid beneficiaries were randomly assigned to prepaid plans. Random samples of individuals with severe mental illness were selected from the prepaid enrollees and from beneficiaries remaining with traditional Medicaid. The two groups were compared with respect to their use of community treatment programs and the write-off (the proportion of patient charges for which payment was not received) experienced by those programs for members of the study sample.

Results. There was no strong evidence that Medicaid beneficiaries with severe mental illness who were randomly assigned to prepaid plans used community-based mental health treatment programs differently than did other Medicaid beneficiaries. However, write-offs were consistently higher for enrollees in prepaid plans.

Conclusions. In the short run, the use of community-based mental health treatment programs need not be affected by enrollment of Medicaid beneficiaries in prepaid plans, providing that Medicaid program administrators take steps to minimize the disruption of ongoing treatment, offer beneficiaries a choice among prepaid plans, and encourage community treatment programs to contract with plans to serve beneficiaries. (*Am J Public Health.* 1992;82:790–796)

Introduction

Proposals to enroll people with severe mental illness, particularly Medicaid beneficiaries, in health maintenance organizations (HMOs) have generated concerns on the part of mental health policy analysts and providers.[1–4] Among these concerns is that beneficiaries enrolled in HMOs will use the mental health treatment programs available in their communities less frequently than do beneficiaries under traditional Medicaid. It is feared that this reduced use, particularly if accompanied by reduced payments to treatment programs by HMOs, will have an adverse effect on the financial viability of these programs. In this article we analyze use and reimbursement of community-based mental health treatment programs on the part of Medicaid beneficiaries with severe mental illness. The experience of beneficiaries randomly assigned to prepaid plans is contrasted with that of beneficiaries in traditional Medicaid. Throughout the article, we use the term *community-based treatment program* to include community mental health centers, crisis centers, day treatment programs, and drop-in centers, all of which are typically major providers of mental health care to indigent populations.

Concerns about the Interface between HMOs and Community-Based Treatment Programs

The manner in which HMOs relate, or might relate, to community-based mental health treatment programs has been a matter of debate.[5,6] A recent survey of the benefits provided by HMOs to their private sector enrollees reported that 53% exclude treatment of chronic mental illness from their standard benefit plan and 64% exclude long-term psychotherapy.[7] These figures suggest that many HMOs may have limited experience in delivering services to severely mentally ill persons and have lead to concerns that HMOs may not take full advantage of community-based programs in treating their enrollees. However, HMO enrollees with severe mental illness may seek out publicly subsidized community-based programs to avoid HMO gatekeepers or to circumvent other HMO policies that restrict access. Such a strategy seems particularly likely for Medicaid beneficiaries, who may be familiar with these programs through past use. In some cases, HMOs may encourage the use of community-based treatment programs through contractual and other, less formal, methods, to reduce their own costs of treating enrollees with severe mental illness.[8,9] An HMO would realize cost reductions if the charges of the community programs were less than the cost of delivering similar services through HMO providers or if the HMO did not fully reimburse the charges billed by these treatment programs.

If the overall use of community treatment programs drops as a result of enrolling Medicaid beneficiaries in HMOs, program supporters fear that public sector subsidies and Medicaid reimbursements will be reduced. Such reductions could force these programs to scale down their activities or, in the extreme, to discontinue their operations. However, program supporters also foresee possible negative consequences, from a public policy standpoint, of *greater* use of community-based programs by HMO enrollees. For example, the public sector might, in effect, pay twice for the mental health care of HMO enrollees: once through general public subsidies provided to the programs and once through the capitation payment made by Medicaid to the HMO, which is intended to

This paper was submitted to the Journal September 30, 1991, and accepted with revisions March 12, 1992.

cover all of the costs of providing care to HMO enrollees. If the programs were reimbursed appropriately by HMOs for services they provided, then, at least in theory, public subsidies to these programs could be reduced so that double paying did not occur and the programs would not be adversely affected. On the other hand, if budget subsidies were reduced by amounts greater than the reimbursements received by community-based programs for treating HMO enrollees, these programs would be faced with the need to provide more services but with fewer resources.

We tested two general hypotheses related to these issues. The first hypothesis was that the use of community-based treatment programs by severely mentally ill Medicaid beneficiaries would differ from the use observed under traditional Medicaid. Given the conflicting arguments that can be made, we did not assign a directional expectation to this hypothesis. Also, we did not address whether reductions in the use of community-based treatment programs would imply poorer quality care or result in worse patient outcomes, even though these are obviously important research issues. The second hypothesis was that the proportion of patient charges for which payment is not received by community-based programs (which we define as the "write-off") would be higher for Medicaid beneficiaries in HMOs than for beneficiaries in traditional Medicaid.

The Hennepin County Demonstration

In 1982, the Health Care Financing Administration authorized six states to enroll Medicaid beneficiaries in prepaid health plans on a demonstration basis. As part of this demonstration, in Hennepin County (Minneapolis), Minnesota, 35% of all Medicaid beneficiaries were randomly assigned to receive services from prepaid plans. They were then provided with assistance in selecting a plan; those who did not make a choice ultimately were assigned to a plan. Enrollment of individuals who were disabled owing to mental illness occurred between November 1986 and April 1987; service delivery for early enrollees began on January 1, 1987.[10]

The four prepaid plans that enrolled beneficiaries in the disabled category were all individual practice association plans. Their sponsoring organizations were Blue Cross/Blue Shield, Hennepin County, the University of Minnesota, and an independent organization affiliated with a local hospital corporation. The Hennepin County plan subcontracted with the county hospital (a major provider of mental health services) and county-subsidized community-based treatment programs for the delivery of mental health care. Blue Cross/Blue Shield also offered access to a broad array of mental health providers, including many community-based programs.

The prepaid plans were reimbursed at 95% of estimated Medicaid costs (projected on the basis of historical trends), with different rates established on the basis of age, sex, Medicare participation, institutional vs noninstitutional residence, and eligibility status. The plans were required to deliver all services covered under traditional Medicaid, including all necessary mental health care; were screened to ensure that they had the ability to provide the required range of mental health services; and were subsequently monitored by the state to ensure that they delivered these services effectively.[11] As part of their participation in the demonstration, they were expected to refer enrollees, as needed, to community-based treatment programs and to reimburse these programs for their services.

In implementing the demonstration, several steps were taken to address the concerns expressed by mental health advocates and providers that the prepaid plans would not be able to develop effective linkages with community-based treatment programs and therefore that the continuity of treatment for patients would be interrupted.[12] For instance, the demonstration administrator in Hennepin County had experience in mental health care, as did staff members in the state demonstration office. Also, the availability of a county-sponsored plan gave beneficiaries an option that provided access to most community-based treatment programs. In addition, enrollees were permitted to switch plans within 60 days of their initial choice, giving them a second chance to select plans that allowed them to maintain their relationships with mental health treatment providers. To minimize transition-related problems, an informal grievance procedure was developed that, in most cases, resulted in the prepaid plan's agreeing to pay for completion of treatment by the original provider or completion of the recommended course of treatment by plan providers. A demonstration advisory group was formed to develop standards for monitoring quality of care, for conducting medical records review, and for managing the special needs of mentally ill beneficiaries. At the end of the first demonstration year, plan contracts were amended to enable enrollees to self-refer to mental health providers without authorization from a family practice physician or a psychiatrist.[13]

At the end of the second program year, which was the first year in which disabled beneficiaries were enrolled in prepaid plans, the Blue Cross/Blue Shield plan withdrew from the demonstration, citing unexpectedly high use of services by plan enrollees. Because of Medicaid administrators' concern about the capacity and willingness of the remaining three plans to assimilate all of Blue Cross' disabled enrollees, these individuals were transferred back to traditional Medicaid, although the overall demonstration continued.

Data and Methods

Study Sample

First, Medicaid recipients aged 18 to 65 years who were classified as disabled were identified from Medicaid records. Then an algorithm based on ICD-9 diagnosis codes and the number and frequency of claims was developed to identify beneficiaries in this group with severe mental illness.[10] Applying this algorithm to Medicaid claims tapes for the 2 years before November 1986 yielded 500 individuals who had been randomly assigned to the prepaid group. However, 104 were excluded from the study for a variety of reasons (e.g., spoke a language other than English, were deceased, had moved out of area). Completed in-person baseline interviews were obtained for 93% of the potential interviewees (369 individuals) in the prepaid group. In a similar fashion, 510 individuals remaining in traditional Medicaid were identified as severely mentally ill, 90 were excluded from the interview sample, and 93% (370) of the remainder were interviewed at baseline.

Follow-up interviews were planned for 1 year after the baseline interview, but when the state discontinued participation on the part of the disabled group effective January 1988, modification of the interview schedule was necessary. For individuals enrolled in prepaid plans, follow-up interviews were administered during the period between notification of the state's intent to transfer them back to traditional Medicaid and 2 weeks following the transfer. Because intake dates for enrollment, and therefore entry into the study, varied, the period between baseline and follow-up interview ranged from 7 to

12 months, with an average length of approximately 11 months. Follow-up data for the comparison group were collected according to the same schedule, with individuals randomly assigned interview dates from 7 to 12 months after their baseline interviews, matching the prepaid group on a one-to-one basis. Follow-up interviews were completed with 354 individuals in the prepaid group and 366 in the traditional Medicaid group, resulting in complete baseline and follow-up data for about 96% of the individuals who completed the baseline survey. As the comparisons in Table 1 indicate, there were no significant differences in demographic characteristics or general use of health services between the two groups.

A second data source was used to supplement the self-report data collected in the in-person interviews. At the follow-up interview, respondents were asked to identify community-based treatment programs they had used since the date of the baseline interview. Record abstractors then visited these programs, beginning approximately 6 months after the date of the follow-up interview to ensure completeness of billing records, and recorded all charges and reimbursements for sample members during the demonstration. Interviews with program administrators suggested that receipt of additional reimbursements for services to sample members was highly unlikely. No baseline data on charges and reimbursements were collected.

Statistical Methods

Both "unadjusted" and "adjusted" differences in mean values of measures of service use and reimbursement were calculated for the prepaid and traditional Medicaid groups. Unadjusted differences are differences in average values for the two groups when no statistical controls are applied for differences in baseline characteristics. The groups were similar at baseline with respect to observable characteristics; this similarity supports the use of unadjusted means in making comparisons with the entire sample. Adjusted differences are the differences that remain after a statistical relationship between the service use or reimbursement variable and the set of covariates listed in Table 2 has been estimated. Adjusted comparisons control for remaining baseline differences in beneficiary characteristics. The use of adjusted differences reduces the variance in the estimate of the difference between the experience of beneficiaries in prepaid plans and that of beneficiaries in traditional Medicaid. When estimating adjusted differences in the use and nonuse of community-based programs, we employed logit analysis and calculated differences by setting independent variables equal to their mean values. When estimating differences in number of visits, we used multiple regression analysis in which the dependent variable was the number of visits reported at the follow-up interview minus the number reported at baseline. By using the change in number of visits to a community mental health program as the dependent variable, we avoided estimation problems that can occur when the distribution of the dependent variable is characterized by a high proportion of zero values, as is the case for visits to some types of treatment programs. The coefficient on the prepaid vs traditional Medicaid variable was interpreted as the difference in the change in the measure for the two groups.

Multiple regression techniques were also used to test hypotheses relating to HMO write-offs. However, because no baseline data on reimbursements were collected, the adjusted difference relates to the average write-off during the period covered, rather than to the change from a baseline to a follow-up value. Because this analysis relates only to beneficiaries with some service use, and there is no concentration of dependent variable values at zero, impacts are not measured in terms of changes from baseline measures.

A drawback to the use of adjusted differences (whether calculated by logit or multiple regression analysis) is that fewer observations are available for analysis because of the cumulative impact of missing values for variables. To minimize the loss of data, mean sample values for independent variables were substituted for missing values; this was done for five or fewer observations for each variable. Where data were missing for dependent variables, observations were dropped from the analysis. Consequently, the sample sizes used in estimating adjusted effects vary; sample sizes are reported in the tables, along with significance levels.

Results

Use of Community-Based Mental Health Treatment Programs

Use of community-based treatment programs was measured on the basis of interview responses at baseline and follow-up; each measure covered the 3-month period prior to the interview. At the baseline interview, a significantly larger percentage of the traditional Medicaid group than of the prepaid group reported visiting a day treatment center (12.90% vs 7.07%), and the difference in average number of visits

approached statistical significance as well (3.47 vs 2.07, respectively). The groups were similar at baseline for other measures of use (Table 3).

A comparison of the unadjusted means for percentage of beneficiaries reporting a visit and average number of visits during the demonstration (Table 3, columns 4 and 5) indicates that prepaid group members used the services less often, but none of these differences were statistically significant (column 6). Two differences approached statistical significance: beneficiaries in prepaid plans reported fewer visits, on average, to community mental health centers (.29 vs .53) and a smaller percentage reported visits to crisis centers (4.18% vs 7.10%).

The number of visits generally declined over the course of the demonstration for the prepaid group, except for drop-in centers, where self-reported use increased (Table 3, columns 7 and 8). There was a reduction of .26 in the average number of community mental health center visits by the prepaid group, compared with an increase of .11 for the traditional Medicaid group; the difference in these changes reached statistical significance at the .07 level (column 9). Changes in the use of day treatment were significantly different at the .08 level, owing to a large decline in the number of visits by the traditional Medicaid group.

Column 10 of Table 3 shows estimates of the difference between the two groups in the probability of using each treatment program during the demonstration, after baseline characteristics of the respondents were controlled for. None of the estimated differences approach statistical significance (column 12). Column 11 presents estimates of differences (prepaid group vs traditional Medicaid group) in the changes in number of visits from baseline to follow-up period when respondent characteristics were controlled for. Again, these estimated differences are not statistically significant.

In summary, these results suggest that the enrollment of Medicaid beneficiaries in prepaid plans had a limited impact on the beneficiaries' propensity to use community-based mental health treatment programs and very little impact on the average number of visits to these programs. A consistent, statistically significant pattern of less use by prepaid group members was not evident when we examined changes from baseline values or when we controlled for the baseline characteristics of respondents in estimating differences.

TABLE 2—Covariates Used in the Estimation of Regression-Adjusted Differences (Measured at Baseline)

	Mean	SD
Prepaid vs traditional Medicaid (proportion prepaid)[a]	.50	.50
Age	41.56	11.61

Attempted suicide (proportion)	.07	.26
Number of days in plan[a]	328.70	52.69
Scores on SADS A–F subscales[a]		

Note. A covariate was also entered that interacted with mental and physical health care admissions and visits.
[a]These baseline characteristics were controlled for in the regression analysis.

Charges and Write-offs for Community-Based Mental Health Treatment Programs

Drop-in and crisis centers were omitted from this analysis because billing records did not exist, were incomplete, or were of questionable reliability. The data on the remaining two programs cover the entire period in which the sample member was a participant in the demonstration, rather than the 3-month recall period used in the analysis of data on service use. The analysis has several limitations. Because comparisons of mean values are reported only for users of services whose records were accessible, the sample sizes are small. Also, the protection provided by randomization does not apply to these comparisons (columns 3 and 4) because they rely only on self-selected samples of individuals who reported some service utilization. Therefore, it is possible that observed differences (column 5) could reflect respondent characteristics as well as demonstration impacts. To address this possibility, we also estimated differences using regression analysis (column 7) to control for selected baseline characteristics (indicated in Table 2), where sample size permitted.

As Table 4 indicates (under the heading "Total"), charges per person were higher, but not significantly higher, for prepaid enrollees than for traditional Medicaid beneficiaries. However, the proportion of the bill not paid (the write-off) was significantly larger for prepaid enrollees (.58) than for traditional Medicaid beneficiaries (.30). As a result, the average reimbursement received for prepaid enrollees was less. The estimated difference in write-off remains approximately the same after adjustments are made for respondent characteristics, and is still significant.

To investigate whether HMOs were hesitant to reimburse for particular treatment modalities or types of providers, we analyzed the data after disaggregation by these variables. Although the sample sizes after disaggregation are small for some categories, all results are reported to facilitate comparisons. When data were disaggregated by type of treatment, prepaid enrollees had higher charges and higher write-offs for psychotherapy, drug therapy, and day treatment. Despite small sample sizes, the difference in write-offs is significant at the .01 level for drug therapy and at the .06 level for psychotherapy after

Note. There are 311 individuals with complete baseline and follow-up data for the prepaid (PP) group and 310 for the traditional Medicaid (TM) group. In columns 3, 6, 9, and 12 the *P* values refer to significance levels for PP–TM differences.

adjustments are made for differences in respondent characteristics.

When data were disaggregated by provider type, write-offs were consistently higher for prepaid enrollees across all provider types; significant differences occurred for physician and "other clinician" write-offs. For these provider types, charges were also higher for prepaid enrollees, but not significantly so. There were enough observations in these two categories to permit estimation of regression-adjusted means as well. The adjusted differences were comparable to the unadjusted differences; the difference for physician write-offs remained statistically significant.

In summary, community-based mental health treatment programs had higher write-offs for Medicaid beneficiaries enrolled in prepaid plans. When data were disaggregated by provider, significant write-offs occurred for treatment by physicians. One possible explanation for this pattern of higher write-offs is that community-based treatment programs attempted to bill prepaid plans at higher rates than are allowed for traditional Medicaid beneficiaries. Charges for prepaid beneficiaries are higher, but the differences in charges are not statistically significant, whereas differences in write-offs are significant. It is important to reiterate, however, that small sample sizes, together with the large variance that exists in average charges, reduce the likelihood that statistically significant differences in the charge data will be observed.

Discussion

With respect to our first general hypothesis, we found no strong evidence that Medicaid beneficiaries with severe mental illness who were enrolled in prepaid health plans used community-based mental health treatment programs any differently than did other Medicaid beneficiaries. There are a number of possible explanations for this finding. First, beneficiaries were enrolled in prepaid plans for less than a year, and this may have limited the ability of the plans to alter the utilization behavior of enrolled beneficiaries. Our interviews with demonstration administrative staff and the staff of the prepaid plans indicate that plan enrollees continued to receive treatment from their predemonstration providers until the end of an illness episode or until transfer to a plan provider was arranged by mutual agreement. Thus at least some beneficiaries were able to continue as clients of community-based programs with little or no interruption even after their enrollment in prepaid plans.

A second explanation relates to the networks of providers available under the different prepaid plans and the freedom that beneficiaries had to choose among the available plans. As noted previously, the Hennepin County plan provided access to most community-based treatment programs, and Blue Cross/Blue Shield's provider network also included many community-based programs. Furthermore, the plans were not allowed to require that enrollees seek a physician referral to access the services of these programs.

The evidence supports the second general hypothesis: write-offs (based on unadjusted means) were significantly higher for prepaid plan enrollees than for other Medicaid beneficiaries across virtually all categories of provider and service. At least some of these differences remained significant after individual characteristics were controlled for, where sample size permitted. However, this conclusion must be interpreted with caution because there may be differences in the baseline characteristics of sample members that were not adequately controlled for in the regression analysis. Also, there is some evidence suggesting that charges were higher for prepaid plan enrollees, as well.

There is a plausible scenario that would explain our finding of no difference between the two groups in the use of community-based programs, along with higher write-offs for prepaid beneficiaries. Program policies encouraged the prepaid plans not to disrupt treatment that was ongoing at the time the demonstration was

Note. PP = prepaid group; TM = traditional Medicaid group. Write-off is defined as (charges minus reimbursement)/charges.

initiated. Policies also did not allow prepaid plans to require prior authorization by a physician for referral to community-based mental health treatment programs; such a requirement is a typical utilization management technique employed by HMOs. The fact that they were not allowed to require such authorization may have caused the prepaid plans to rely heavily on retrospective denial of payment for services rendered by community-based programs as a means of controlling expenditures. Some programs may have accepted higher write-offs for prepaid enrollees because the subsidy they received from the public sector was based in part on the volume of services they provided. In fact, two prepaid plans attempted unsuccessfully to negotiate reimbursement rates with community-based programs, leading these plans to conclude that the programs had little incentive to aggressively pursue private reimbursement for the services they provided.[13] □

Acknowledgments

Financial support for this research was provided by Hennepin County (Minnesota), the National Institute of Mental Health, the Bush Foundation, the state of Minnesota, and the Hennepin Faculty Associates Young Investigators Program. Dr Lurie is a Henry J. Kaiser Family Foundation Faculty Scholar in general internal medicine.

The authors wish to thank the administrators of community-based treatment programs in Hennepin County for providing access to financial data; the staff of Hennepin County and of the Medicaid program in the State of Minnesota for facilitating access to Medicaid records and for providing their support for the research; and the administrators of the prepaid plans and the Medicaid beneficiaries in our sample for their willingness to participate in in-person interviews. We also acknowledge the excellent assistance in data collection provided by Colleen King and Susan Ricketts.

Commentary: Caring for the Indigent Mentally Ill—New Strategies and Old Problems

ABSTRACT

Christianson and his colleagues examine how Medicaid beneficiaries receive mental health services in HMOs by analyzing two important aspects of service delivery: the use of community-based treatment programs by Medicaid beneficiaries enrolled in health maintenance organizations (HMOs) and the reimbursement levels paid to these programs by HMOs. The hypotheses studied are complex issues that concern mental-health advocates and providers. Traditional community-based mental health services have always struggled to maintain their presence in the health care field, having to contend with changing funding priorities and more serious and multiple problems presented by their patients. For prepaid plans to work effectively for the indigent mentally ill, the complex issues have to be made clear and acknowledged as meaningful variables. (*Am J Public Health*. 1992;82:796–798)

Ernesto Ferran, Jr, MD

Dr Christianson and his colleagues analyze two important aspects of mental health care delivery for those who have serious mental disorders and are indigent.[1] They want to know whether Medicaid beneficiaries, once enrolled in prepaid medical plans, will utilize mental health services to the same degree as do non-enrolled Medicaid beneficiaries, and whether the plans will pay the mental health providers the amounts requested of them. Advocates for the indigent mentally ill population would define these questions as questions of access to mental health services and protection of funding for providers traditionally vulnerable to new financing schemes. The issues are not only complex, but also mysterious, and they lend themselves to contentiousness and partisanship.

What I want to address are the factors that make these issues complex: the fact that psychiatric standards of care are difficult to quantify; that mental health care providers, in the absence of conclusive outcome studies for traditional services, are promoting new strategies for providing services to the seriously mentally ill; and that agreement on reimbursement for these strategies will continue to be elusive.

By addressing their first question without a directional hypothesis, the authors avoid being drawn into the argument that relates utilization of outpatient mental health care to outcome. It makes sense that they do so: our fascination with health care expenditures as an object of study or control becomes problematic for disorders of behavior, emotion, or thought, and the relevant standards of care continue to be poorly understood. Consider the near decade-long effort to create adequate diagnosis-related groups for psychiatric disorders. Witness the relatively recent controversies surrounding for-profit psychiatric hospitals, and the accompanying arguments on appropriate inpatient care vs expected or egregious pricing strategies. Have you not wondered, at some point, what it is that the most vulnerable segment of America's homeless really needs—housing, employment, or long-term psychiatric inpatient care? In other words, the quest to quantify robust standards of care for psychiatric disorders continues to generate more controversy than consensus.

The second hypothesis almost speaks for itself: Write-offs will be higher because prepaid plans will not pay the full costs of care. Why wouldn't they? Why even consider that they wouldn't? If outcome data for outpatient mental health services are so scant, and if "managed-care" pricing strategies (e.g., using diagnostic categories to determine allowable units of service) are de-

Weight Gain Prevention and Smoking Cessation: Cautionary Findings

ABSTRACT

Objectives. Weight gain is a consistent sequela of smoking cessation. A successful intervention might attract smokers who fear weight gain. If the gain causes smoking relapse, such an intervention might reduce smoking relapse risk.

Methods. Using a sample of 158 smokers who completed a 2-week smoking treatment program, we compared an innovative weight gain prevention intervention with both a nonspecific treatment and standard treatment. Subjects were assessed on weight and smoking behavior and followed for 1 year.

Results. A disturbing, unexpected finding was that subjects in both the innovative and nonspecific conditions had a higher risk of smoking relapse than did standard treatment subjects. Some differences were observed between abstinent and smoking subjects in weight gain by treatment condition.

Conclusions. Both active interventions may have been so complicated that they detracted from nonsmoking. Also, caloric restriction may increase the reinforcing value of nicotine, a psychoactive drug, thereby increasing smoking relapse risk. The magnitude of weight gain after smoking cessation may not merit interventions that increase smoking risk. Perhaps attitudinal modifications are the most appropriate. (*Am J Public Health.* 1992;82: 799–803)

Introduction

Weight gain is a consistent sequela of smoking cessation. Of 43 studies of weight change after smoking initiation or cessation, 37 (86%) report that initiation of smoking reduces weight and cessation increases it. The cause of the relationship between smoking cessation and weight gain is unknown although changes in both metabolism and food intake are implicated. Smokers, especially young women who smoke, are aware of nicotine's weight-suppressing effects.[1] Nevertheless, studies of the effects of weight gain on relapse sometimes report surprising findings. For example, investigators[2–4] have found that weight gain during early abstinence predicted long-term abstinence, not relapse.

A successful intervention for weight gain prevention might attract smokers who fear weight gain and could potentially reduce relapse. In those few cases in which weight gain would be sufficient to pose a medical problem, such an intervention would prevent increased risk.

We designed an innovative intervention based on a model that suggests that adherence to behavioral prescriptions is facilitated by simplicity and by a close fit between self-management techniques and the problem behavior.[5] In this study, we report a comparison of this intervention with nonspecific and standard treatment conditions. The nonspecific condition was equiva ent to the innovative condition in time and therapeutic attention. The standard treatment control condition was designed to represent standard care of cessation-induced weight gain.

We proposed the following hypotheses: (1) Abstinent smokers in the innovative intervention would gain less weight than those in the nonspecific intervention, who would gain less weight than abstinent smokers in the standard treatment control condition. (2) Abstinence rates in the innovative intervention would be greater than those in the nonspecific intervention or in standard treatment because the close fit of the therapeutic techniques to cessation-induced gain in the innovative condition would be less likely to interfere with abstinence.

We also examined activity levels and, in a subsample, changes in food intake to determine whether subjects adhered to the instructions in the interventions.

Methods

Subjects and Personnel

Subjects were 49 male and 131 female smokers, all of whom met at least one of two risk factors for weight gain: they had to have smoked at least 10 cigarettes per day in the past week or been at least 10% above ideal weight at their maximum.[2] We excluded potential subjects with cardiovascular or pulmonary disease, diabetes, hospitalization for major mental illness within the last year, or any chronic condition that would influence eating or activity levels. Of these 180 subjects, 165 (92%) completed the smoking cessation treatment and were randomized to one of the weight gain prevention interventions.

The authors are with the University of California and the Veterans Affairs Medical Center in San Francisco.

This paper was submitted to the Journal June 10, 1991, and accepted with revisions November 12, 1991.

There were four female therapists. Two, a master's-level social worker and a doctoral-level psychologist, treated 159 (88%) of the subjects. The other two therapists were a master's-level health educator and a master's-level psychologist. Before beginning the intervention, therapists led at least one training group and observed other therapists' groups. During the intervention, therapists followed a detailed procedures manual. Two female registered dietitians and a male exercise consultant also participated.

Assessments

Assessments were held at pretreatment, at week 2 (the end of smoking treatment), at week 6 (the end of the weight gain prevention intervention), and at weeks 12, 26, and 52 from study start. At each assessment, subjects reported the average number of cigarettes smoked per day in the past week and provided expired air carbon monoxide samples to verify abstinence. At pretreatment and at the week 52 assessment, blood cotinine levels were determined as well. During each assessment week, subjects monitored their activity levels by recording time spent in bouts of activity on a schedule of 49 activities developed from McArdle, Katch, and Katch.[6] Body weights were taken at all assessments on the same balance beam scale. Twenty-four-hour dietary recalls, later processed for nutrient analyses by Nutrition and Diet Services,[7] were obtained from the last 91 subjects to enter the study. At baseline, subjects indicated the number of times they had attempted to quit smoking, their weight gain during past attempts, and whether they were concerned about and expected weight gain during the current attempt.

Procedure

Subjects were randomly assigned, within their time constraints, to groups of five to eight participants. During weeks 1 to 2, all groups received a smoking treatment program of seven 1½-hour sessions that combined aversive smoking and relapse prevention skill training. Until the last smoking treatment session, both therapist and group members were blind to which weight gain prevention intervention the group was assigned.

Subjects assigned to the innovative and nonspecific interventions participated in five weight gain prevention sessions held during weeks 3 to 6. During these sessions, discussions of purely smoking-related phenomena were minimized to focus on weight gain prevention and to keep about equal the amount of time spent on smoking cessation in the three conditions. Other than the assessment at week 6, no meetings were held in the standard treatment condition during these 4 weeks.

Innovative Intervention. There were three components to this intervention.

1. Daily monitoring of weight and contingent caloric reduction. Before the first session of the intervention, the dietitian computed for each subject a calorie level (the "food plan") designed to result in a weight loss of 2 lb per week based on body weight, age, sex, and activity level. The dietitian discussed healthy food choices and provided tips on low-calorie, sweet-tasting foods and on low-fat alternatives to common foods. Subjects weighed themselves each morning without clothing. If their weight was within 2 lb of baseline weight, they ate whatever they liked; if they gained 2 lb or more, they were to use their food plan until baseline weight was achieved.

2. Individualized exercise plan. The exercise consultant explained the principles of aerobic exercise and the benefits of fitness, and he helped subjects select an activity. Subjects were encouraged to exercise three or more times a week at an aerobic level.

3. Behavioral self-management principles. The subjects discussed triggers that resulted in uncontrolled eating. If appropriate, new responses were role-played. Subjects were asked to limit eating to one place at home and at work, and to slow eating by taking a single bite at a time.

Nonspecific Control. The nonspecific control condition included the elements of a credible weight gain prevention intervention without the specific elements of the innovative condition. The nonspecific elements were (1) a rationale based on gaining insight into eating styles, (2) a structured program based on insight-oriented discussion, (3) nutritional and exercise information, (4) group support, and (5) therapeutic attention. The sessions centered around both self-tests adapted from the Smokers' Self-test Kit[8] and informational presentations by the nutritionists and the exercise consultant. The dietitian presented general nutritional information about calories and good nutrition, noting that caloric reduction was necessary for weight loss. The fitness consultant presented fitness principles and the health benefits of exercise. However, there was no attempt to individualize the information. The therapist did not give specific behavioral prescriptions. Rather, she encouraged subjects to decide how they would use feedback provided by the group, and she referred questions about specific techniques back to the group. The number and spacing of sessions were the same as those in the innovative condition.

Standard Treatment Control. Subjects received an information packet on good nutrition and exercise at the last smoking treatment session. This material was not targeted for smoking cessation–induced weight gain.

Results

Preliminary Analyses

As previously noted, 165 of the 180 subjects who began treatment completed the smoking cessation portion. Dropouts did not differ from the rest of the sample in age, gender, ethnicity, level of education, socioeconomic status, number of previous quit attempts, cessation-induced weight gain, pretreatment carbon monoxide, cigarette intake, or body weight. The data from one subject of each pair of six close relatives were randomly selected to use in the data analyses. Data from an additional subject who was later diagnosed as bulimic were discarded. Resultant sample size was 158. Sizes by intervention condition were innovative intervention, 53; nonspecific control, 51; and standard treatment control, 54. When asked if they expected to gain weight after quitting, 112 of these 158 subjects (71%) said yes. One hundred thirty-eight (87%) reported at least one earlier quit attempt, 86 of whom (62%) reported a weight gain that averaged 6.35 kg (SD = 3.86 kg). Almost all the subjects (92%) were concerned about gaining weight when they quit.

Treatment conditions were compared on the same demographic, smoking, and weight history variables used to compare treatment completors and dropouts, as well as on postcessation body weight and postcessation cigarette smoking rates (see Table 1). Only two differences emerged. First, conditions differed on mean number of cigarettes reported smoked per day during the pretreatment week ($F[2,155] = 5.06$, $P < .01$). Subjects in standard treatment smoked significantly more cigarettes than did those in the other two conditions. Second, the three conditions had significantly different variances on pretreatment body weight ($P < .01$). Subjects in the innovative condition had a significantly greater variance in both these measures than did subjects in the nonspecific condition. In tests of the hypotheses, these variables—pretreat-

ment smoking rate and pretreatment body weight—were used as covariates in preliminary analyses if they correlated with the dependent variable, and they were dropped if they did not explain significant proportions of variance or have significant interactions with independent variables. Due to a lack of significant main effects, or interactions, these variables were ultimately dropped from all analyses, except those of abstinence status. No differences due to therapists were found when the main effects of therapist on smoking rate or body weight were examined.

Abstinence Status

At each assessment, subjects were coded as abstinent if they reported no cigarettes smoked during the prior week and had a carbon monoxide level below 10.5 ppm at the assessment. At week 52, subjects were coded as abstinent only if their blood cotinine levels were also less than 50 ng/mL. Chi-squares of abstinence status by treatment condition did not reach significance at any assessment (Table 2).

However, treatment conditions differed at baseline on number of cigarettes smoked, and baseline number of cigarettes did correlate with abstinence status at the followup assessments. The prototypical analysis was a multiple logistic regression with gender and number of cigarettes smoked at pretreatment as covariates. The dependent variable was abstinence status at each assessment week. Subjects with missing data were coded as smoking. These analyses indicated that, at weeks 6, 12, 26, and 52, treatment condition contributed significantly to the abstinence rate. Subjects in the two active interventions had a greater risk of smoking than did subjects in the control condition. Effects for the two active treatment conditions did not differ from one another.

The odds ratios, associated confidence intervals (CIs), and probability levels are shown in Table 3. The nonspecific condition differed significantly ($P \leq .05$) from the control condition at weeks 6, 12, and 52; the innovative condition differed significantly from the control at week 26. The combined active treatment conditions differed significantly from the control at each assessment.

Smoking more than 35 cigarettes per day at pretreatment significantly increased the risk of relapse at all assessments. The odds ratio ranged from 2.73 at week 6 (95% CI = 1.64, 4.57; $P < .001$) to 1.95 at week 52 (95% CI = 1.08, 3.52; $P < .03$). There were no significant effects for gender at any assessment.

*Comparison with control, $.05 < P < .10$.

Weight Change

The heterogeneity of variances in the weight data was not correctable by either logarithmic or square root transformations. We used a series of Kruskal-Wallis nonparametric analyses of variance on body weight change from week 2 to week 6 and to week 52 to determine if subjects differed by conditions and abstinence status. Kruskal-Wallis tests were also used to establish the lack of difference between conditions and smoking versus nonsmoking subjects on weight change from week 0 to week 2.

There were no differences among treatment conditions on weight change at either week 6 or week 52. Abstinent subjects differed from smoking subjects at both week 6 ($\chi^2[1] = 10.85$, $P < .01$; abstinent subjects, n = 78, mean = +0.79 kg, SD = 1.74; smoking subjects, n = 74, mean = +0.14 kg, SD = 1.32) and week 52 ($\chi^2[1] = 7.21$, $P < .01$; abstinent subjects, n = 31, mean = +2.59 kg, SD = 3.76; smoking subjects, n = 87, mean = +0.22 kg, SD = 3.42). Differences between abstinent and smoking subjects were not consistent across the three conditions, however. In the innovative condition, abstinent and smoking subjects did not differ at either week 6 (abstinent subjects, n = 26, mean = +0.08 kg, SD = 2.4; smoking subjects, n = 24, mean = 0.14 kg, SD = 1.26) or week 52 (abstinent subjects, n = 10, mean = +0.86 kg, SD = 3.95; smoking subjects, n = 35, mean = –0.31 kg, SD = 3.57). Differences between abstinent and smoking subjects were found in the nonspecific condition at both week 6 ($\chi^2[1] = 8.66$, $P < .01$; abstinent subjects, n = 21, mean = +1.20 kg, SD = 1.18; smoking subjects, n = 27, mean = +0.03

[a]In the present study, the odds ratio is interpreted as the change in risk of relapse to smoking that is attributable to membership in the innovative or nonspecific condition, as compared with membership in the standard treatment control.

kg, SD = 1.39) and week 52 ($\chi^2[1] = 4.12$, $P < .04$; abstinent subjects, n = 7, mean = +3.35 kg, SD = 2.38; smoking subjects, n = 25, mean = +0.44 kg, SD = 3.60). The standard treatment control showed no differences at week 6 ($\chi^2[1] = 1.40$, $P < .29$; abstinent subjects, n = 31, mean = +1.12 kg, SD = 1.54; smoking subjects, n = 23, mean = +0.55 kg, SD = 1.27). However, differences in this condition approached significance at week 52 ($\chi^2[1] = 3.45$, $P < .06$; abstinent subjects, n = 14, mean = +3.61 kg, SD = 3.99; smoking subjects, n = 27, mean = +0.71 kg, SD = 3.09).

Calories and Activity Levels

Of the original subsample of 91 subjects on whom we attempted to collect nutritional data, 68 (75%) completed dietary recalls at every assessment and were therefore included in the repeated measures analyses of caloric intake. These subjects did not differ from either the whole sample or the sample of 91 on whom we attempted to collect data on cigarettes smoked or body weight.

An unacceptable level of heterogeneity of variances in baseline caloric intake was reduced to an acceptable level by a square root transformation. The major analysis was a repeated measures analysis of variance. The dependent variables were the square root transformation of caloric intake at baseline and at weeks 6, 12, 26, and 52. Independent variables were gender, treatment condition, and abstinence status at week 52.

A significant effect for treatment condition over time ($F[8,224] = 3.90$, $P < .001$) was found, as was a significant abstinence status × treatment condition × time interaction ($F[8,224] = 2.04$, $P < .05$). We found significant treatment effects at week 6 ($F[2,15] = 11.95$, $P < .01$) and week 26 ($F[2,15] = 2.92$, $P < .01$) but not at baseline, week 12, or week 52. At week 6, subjects in the innovative condition ate significantly fewer calories than those in the nonspecific condition ($t[42] = 2.48$, $P < .03$; innovative condition, mean = 1687 cal, SD = 707; nonspecific condition, mean = 1810 cal, SD = 604) and those in the standard treatment control ($t[42] = 4.29$, $P < .01$; mean = 2817 cal, SD = 976). Differences in caloric intake between the nonspecific treatment condition and the standard treatment control were not significant ($t[46] = 1.83$, $P < .10$). At week 26, none of the paired comparisons was significant.

For subjects smoking at week 52, the time × treatment condition interaction was significant ($F[8,164] = 2.77$, $P < .01$). There were also significant treatment condition × gender interactions at baseline ($F[2,41] = 3.65$, $P < .04$), explained primarily by significantly greater caloric intake by men in the innovative condition than by subjects of either gender in any of the five other gender-treatment condition groupings. Repeated measures analysis of variance indicated no significant effect for activity level.

Discussion

The higher smoking rates at follow-up in the two conditions that received an active treatment are troubling. The odds ratios for the risk of smoking for the two active treatment conditions combined were consistently and significantly greater than the odds ratios for the control condition at each assessment after week 2. The most likely explanation for this is that both interventions were sufficiently complicated so that subjects' attempts to apply them detracted from attempts to maintain abstinence. A second explanation is that the caloric reduction encouraged by both active conditions encouraged smoking. Caloric restriction may increase the reinforcing value of psychoactive drugs in laboratory animals.[9]

The failure to find a significant difference between abstinent and smoking subjects in the innovative condition suggests that this condition prevented weight gain, especially when this lack of difference is compared with the significant differences found between abstinent and smoking subjects in the nonspecific condition. Differences in the control condition, however, also failed to reach significance, rendering interpretation tentative. In the innovative condition there was evidence of early compliance with dietary instructions, especially among women and abstinent subjects. The interventions had no measurable affect on self-reported activity.

The limitations of this study are important. First, the results obtained apply to one program; other programs may be more successful. Second, the finding of increased relapse rates in the two active treatment conditions must be viewed with caution. The design of the study, in which differing combinations of behavioral therapists, nutritionists, and exercise therapists treated subjects in each condition, did not lend itself to a thorough analysis of intervenor × treatment condition interaction effects. These effects are known to influence the magnitude of differences among treatment conditions, at least in traditional analysis of variance models.[10] So far as we could find, nothing has been published about these effects in logistic models. Inspection of the data and those analyses we did perform did not suggest consistent intervenor effects, and significant main effects for intervenors were not found. Such analyses, however, cannot substitute for a complete factorial analysis of their differences.

Finally, it should be noted that the average gain for ex-smokers over 1 year is about 4 lb greater than that expected for continuing smokers. One study reported that about 3% of quitters gained 20 lb or more.[11] Such small weight gains do not appear to merit interventions that are extensive or entail risk. Perhaps attitude

changes about weight gain are more appropriate interventions than treatment of that gain. □

Acknowledgments

This study was funded in part by grants DA02356 and DA00065, both from the National Institute on Drug Abuse, and by a Research Career Scientist Award from the Department of Veterans Affairs to Dr. Hall.

Call for Abstracts for First International Conference on Community Health Nursing Research

The International Scientific Review Committee invites interested nurses to submit abstracts of papers or posters for presentation at the First International Conference on Community Health Nursing Research, to be held September 27 to 29, 1993, in Edmonton, Alberta, Canada. Papers and posters that deal with the development, design, or implementation of research in community/public health nursing and primary health care are welcome. The deadline for abstracts is *September 15, 1992.*

For abstract submittal forms and further information on the conference, contact the International Conference on Community Health Nursing Research, Edmonton Board of Health, Suite 500, 10216 - 124 St, Edmonton, Alberta, Canada T5N 4A3; tel. (403) 482-1965, fax (403) 482-4194.

Call for Abstracts for the Sixth International Conference on Indoor Air Quality and Climate

INDOOR AIR '93, the principal international conference on indoor air quality, will be held July 4 to 8, 1993, in Helsinki, Finland. The conference will offer an overview of the latest research results in the field, and anyone who is seriously involved in technological development, building sciences, regulatory issues, or other businesses related to indoor air is encouraged to attend.

Topics to be covered include public health, biosciences, occupational health, environmental engineering, building design and technology, energy consumption, building operation, material sciences, air chemistry, and regulatory issues.

Abstracts must be received by *October 1, 1992.* For a complete list of topics, an abstract submittal form, and further information on the conference, contact INDOOR AIR '93, PO Box 87, SF-02150 Espoo, Finland; fax 358 0 451 3611.

Improving Referral Compliance after Public Cholesterol Screening

ABSTRACT

Background. Noncompliance with referral to a physician for retesting and diagnosis is a concern in public cholesterol screening.

Methods. Participants (n = 2109) were referred by a health professional or lay communicator and randomly assigned to a coupon offer, referral reminder letter, or control group. A questionnaire was completed at screening, and a telephone interview was conducted 5 months later.

Results. Physician visit rates showed no professional or lay differences. For "no history" subjects, the behavioral interventions were effective compared with controls (coupon = 60.7% and reminder = 57.7% vs control = 46.1%). With professional counseling, only the coupon was effective; for lay counseling, both coupon and reminder yielded higher visit rates. Adjusted for sociodemographics, heart disease risk factors, and health perceptions, the intervention effects remained (professional–coupon offer: odds ratio [OR] = 1.94, 95% confidence interval [CI] = 1.21, 3.09; professional–reminder letter: OR = 1.04, 95% CI = 0.67, 1.63; lay–coupon offer: OR = 2.52, 95% CI = 1.52, 4.18; and lay–reminder letter: OR = 3.10, 95% CI = 1.83, 5.22).

Conclusions. For unaware participants, lay counselors and referral follow-up efforts tailored to specific cholesterol risk groups are indicated. (*Am J Public Health.* 1992;82:804–809)

Introduction

The National Cholesterol Education Program (NCEP) recommends blood cholesterol testing for all adults and has attempted to inform the public about the significance of high blood cholesterol levels in heart disease.[1] This effort and the recent availability of portable rapid cholesterol analyzers has led to increased participation in public screening.

Unanswered questions about mass cholesterol screening programs led the 1984 Consensus Development Conference to call for further research on the utility of these programs in order to formulate guidelines for public cholesterol screening under quality conditions.[2] Primary issues of concern were (1) whether screening can effectively link participants with elevated cholesterol to medical care, (2) whether physicians treat referrals according to current guidelines, and (3) the reliability of portable analyzers over extended time periods in screening field-type conditions.[3] Previous studies indicate that only 29% to 57% of participants with elevations follow through on referrals from public cholesterol screenings[4–6] and that physicians retest 33% to 48% who seek care.[4,7] The lack of acceptable accuracy and standardization in cholesterol measurement has been noted.[3]

As one of three Model Systems for Blood Cholesterol Screening Projects supported by the National Heart, Lung, and Blood Institute (NHLBI), the Rochester Project addressed all of these concerns. The present report focuses on interventions to increase referral compliance. The results concerning the increased responsiveness of physicians and acceptable reliability of portable analyzers have been reported elsewhere.[8,9]

The study examines whether health professional counselors at screening and follow-up interventions affect compliance with referral for retesting and diagnosis. The contributions of sociodemographic characteristics, coronary heart disease risk factors, and health motivations are also assessed.

Methods

Setting and Design

Voluntary, free cholesterol screenings were conducted in supermarket parking lots in Rochester, NY. Table 1 summarizes the study design. Participants, 20 through 65 years of age and meeting age-specific criteria for moderate- or high-risk cholesterol levels, were referred to a physician for retesting and diagnosis. Ineligibility occurred if conditions capable of causing cholesterol elevations were reported (pregnancy or lactation, or diabe-

[e]Five months after screening.

tes, liver disease, or hypothyroidism). Individuals without a regular source of medical care received a list of primary care physicians accepting new patients. Informed consent and a medical release for physician verification of cholesterol treatment were obtained at screening.

Total serum cholesterol was determined using a finger-stick blood sampling, and analyses were done on the Eastman Kodak Ektachem DT-60. Following standard procedures for quality control recommended by the Laboratory Standardization Panel of NCEP,[10] the between-run coefficients of variation ranged from 1.9% to 4.8% per month; average bias compared with the Abell-Kendall Reference Method ranged from −0.2% to 2.0%. Both precision and accuracy met recommended standards for cholesterol testing in the United States.[9]

At the initial level of the 2 × 3 factorial design, each participant received counseling from the first available health professional (i.e., nursing background) or lay communicator. Participants were unaware of the counselor's background. After each screening shift, referred participants were randomly assigned to a coupon offer, reminder letter, or control group.

Participants completed a self-administered questionnaire prior to receiving their test result and were interviewed by telephone approximately 5 months after the screening. If telephone contact was not made, a questionnaire was mailed. From June through October 1987, 7824 individuals were screened and 2109 referred. The follow-up survey involved 1975 subjects, and 1948 with complete data (92%) were included in the analyses. The cohort of referred participants unaware of elevated levels prior to screening (n = 1187) is the primary focus of this paper. Since public screening attracts individuals with known elevations, comparative findings for this subgroup (n = 761) are presented without tabular data in the interest of brevity.

To limit subject and communicator bias, the consent form described the survey as determining experiences after screening, the questionnaire and interview inquired about general health information as well as cholesterol-specific items and physician visit, and the communicators were "blind" to the interventions. Finally, interviewers were "blind" to a subject's intervention and screening risk group.

Measures

Predictor measures. The baseline questionnaire obtained data on sociodemographics, personal medical history of high blood cholesterol and other coronary heart disease risk factors, intention to visit a doctor if the cholesterol test was high, and perceptions of health and medical care. Screening cholesterol risk level for referral was defined according to age by blood concentration guidelines recommended at the time of the program (moderate risk: 20 through 29 years = 200 to 220 mg/dL; 30 through 39 = 220 to 240 mg/dL; 40 or over = 240 to 260 mg/dL; high risk: 20 through 29 = >220 mg/dL; 30 through 39 = >240 mg/dL; 40 or over = >260 mg/dL).[2]

Experience of counselor. Since messages for those with and without elevations were s[illegible]n content, except for the recommendation to consult a physician, experience of counselor was based on the total number of interactions. A categorical measure of counseling experience was defined for each referred subject by placement in his or her counselor's experience level across all participants counseled (1 = 1 through 74; 2 = 75 through 199; 3 = 200 through 299; 4 = 300 through 499; and 5 = ≥500).

Outcome measure. The follow-up interview asked whether participants had contacted their doctor about the screening test. A dichotomous dependent variable reported the proportion in each intervention group actually visiting their physician.

Self-reports and medical record data were compared for participants reporting a physician visit and identifying the source of care (n = 1082; 94%); 337 of 367 physicians returned record forms for 1001 subjects (completion rates of 92% and 93%, respectively). Physician documentation corroborated with 94% of the self-reports.

Interventions

Monitoring procedures ensured the correct-for-risk-level counseling and the accurate implementation of the follow-up interventions.

1. "Exit counseling communicators," half professional and half lay (n = 22), received the same length and content of training and served throughout the project. Counseling (3 to 5 minutes) included the following: cholesterol level and interpretation as "usual," "moder-

ate," or "high" risk; susceptibility to heart attack as a consequence of high cholesterol; and benefits of diet and drug therapy for lowering cholesterol. Participants with elevations were advised to see their doctor for retesting and diagnosis. Handouts containing this information were provided.

2. A letter restating the referral and explaining a coupon offer totaling $17 for heart-healthy foods, redeemable at the sponsoring supermarket for each participant adhering to the referral, was mailed approximately 3 days after screening.

3. The reminder letter reemphasized the referral, described the association between elevated cholesterol and heart attack and the benefits of physician-directed treatments to lower cholesterol, and included a cue to action (screening level and risk group). It was mailed approximately 3 days after screening.

Analysis

Analyses were stratified by history of high blood cholesterol. Bivariate contingency table analyses compared the unadjusted rates of referral compliance between communicator conditions overall and within each second-level intervention group. Multiple logistic regression analyses with backward selection were performed to identify significant covariates for inclusion in the final model; variables included communicator type and behavioral interventions and their interaction. Adjusted odds ratios (ORs) were estimated by exponentiating the maximum likelihood estimates of the parameters (beta coefficients), and asymmetric 95% confidence intervals (CIs) were calculated using the asymptotic standard errors of the coefficient estimates.[11]

After intervention variables and their interactions were entered, the final model included dichotomous variables for marital status, screening cholesterol risk level, and history of high blood pressure and heart condition; cigarette smoking was included as a categorical variable. Continuous variables included were counseling experience, age, obesity (Quetelet's index), and 5-point measures for intention to see a doctor if cholesterol is high (1 = "very likely," 5 = "not likely at all"), perceptions of difficulty to see a doctor (1 = "strongly agree," 5 = "strongly disagree"), and "current health" (summated score of agreement for "somewhat ill," "health is excellent" [reversed scale], and "feeling bad lately"; range = 3 to 15; Cronbach alpha = .73). We used SAS for bivariate analyses and Biomedical Data Processing (BMDP) for logistic regression.

Results

Participant Characteristics

There were no differences in sociodemographic characteristics or coronary heart disease risk factors between counselor types or among the six study groups. There were three sociodemographic differences between history groups: "no history" subjects were younger, somewhat more educated, and less likely to be married (Table 2). As expected, fewer unaware subjects had any particular major coronary heart disease risk factor.

Compared with the adult population of Rochester and its suburban areas, referred subjects were more likely to be White, older, and female and to have higher levels of education.[12] Only 16.2% of unaware and 12.3% of "prior history" subjects were current smokers compared with approximately 25% of both the total screened and Rochester area populations.[13]

Communicator and Behavioral Intervention Comparisons

Within 5 months after screening, 1156 referred subjects (58.5%) visited their physician: 645 (54.8%) of the no history group and 499 (66%) of the prior history group. For no history subjects, communicator type yielded no overall unadjusted effect on the proportion seeking medical care (Table 3). An impact of both behavioral interventions was observed, with the coupon and reminder about equally effective

($P < .0001$). Only the coupon offer enhanced compliance with professional counseling ($P = .02$), while for lay communicators both behavioral interventions were effective ($P < .0001$).

Stratification by behavioral interventions revealed communicator differences only for the reminder: the lay–reminder condition produced the highest level of referral compliance (66.7%, 95% CI = 59.7, 73.6), which was above the upper limit of the 95% CI of the professional–reminder group (50.2%; 95% CI = 43.5, 56.9) ($df = 1$, $P = .001$). Finally, prior history subjects were generally 10% to 15% more likely to have visited a physician, but neither communicator type nor behavioral interventions significantly increased outcome (data not shown).

Adjustment for Covariates

The final adjusted stepwise regression analysis in Table 4 shows that, for unaware subjects, the presence of covariates in the model did not alter the interaction between communicator type and behavioral interventions and differences in compliance rates ($P = .005$). With professional counseling, coupon offer subjects were more likely than control subjects to comply with the referral; the reminder letter was not effective. The behavioral intervention effect was most evident for lay-counseled subjects: both the coupon offer (OR = 2.52, 95% CI = 1.52, 4.18) and the reminder letter (OR = 3.10, 95% CI = 1.83, 5.22) were associated with an increased likelihood of a physician visit.

Older subjects and those with other coronary heart disease risk factors were slightly more likely to have visited a physician. High compared with moderate screening risk level and expression of a greater intention to seek medical care for an elevated test were associated with compliance.

In the model for prior history subjects (data not shown), no differences in seeking medical care were associated with either communicator type (OR = 1.03, 95% CI = 0.73, 1.45) or follow-up interventions (coupon offer: OR = 1.16, 95% CI = 0.77, 1.76; reminder letter: OR = 1.32, 95% CI = 0.87, 2.01). Receipt of counseling from a more experienced communicator, being older, and currently having a spouse or partner emerged as weak predictors, as well as high risk level and a history of high blood pressure. The most powerful predictor was greater intention to seek medical care (OR = 0.70, 95% CI = 0.59, 0.82, $P < .0001$).

[d]Difference among behavioral intervention groups $P = .02$ by χ^2 test, $df = 2$.

To further investigate the interaction in the no history group, alternative unadjusted models, assuming that various combinations of the six study group rates were equal, were evaluated (data not shown). A satisfactory fit was obtained ($\chi^2 = 5.88$, $df = 4$, $P = .21$) for a model that assumed similar compliance rates for the professional and lay coupon groups and the lay–reminder group, as well as the two control groups and the professional–reminder group. The combined rate for the coupon offer and lay–reminder groups was 62.5%, while the other three groups had a rate of 47.6%. A simpler hierarchy of follow-up interventions resulted compared with the observed data (Table 3).

There were no differences in rates of participants seeking care due to variations in effectiveness among counselors. Individual counselor rates for no history subjects were inconsistent across follow-up intervention groups. Removal of three lay counselors with a greater proportion of compliant referrals in the reminder condition diminished the lay–reminder effect; however, both behavioral interventions maintained higher visit rates (lay–coupon offer = 62.5% and lay–reminder letter = 59.3% vs lay–control = 40.5%; $P < .0001$). Finally, differences in participant characteristics in the lay–reminder group did not contribute to the interaction.

Discussion

A 1990 national survey estimates that 29 million US adults have attended public cholesterol screenings.[14] The inadequacy of counseling and lack of physician referral has been cited by the Office of the Inspector General.[15] The present study, which contributed to the NHLBI Workshop on Public Screening for Blood Cholesterol recommendations,[16] provides support for practical counseling and follow-up strategies that can be adopted by other screening programs to increase the chances of those referred seeking appropriate retesting and diagnosis.

Screening with immediate cholesterol assessment provides a teachable moment in which participants are highly receptive to coronary heart disease and dietary education and referral messages.[17] Findings substantiate the hypothesis of no differences in counseling effectiveness between professional and lay communicators. Consistent with other studies showing that lay individuals performed comparably to health professionals in influencing health attitudes and behaviors,[18,19] these results have implications for those planning screening. Lay counselors are more accessible and less costly to train and employ than health profes-

TABLE 4—Logistic Regression Model of Factors Associated with High Blood Cholesterol Screening Referral Compliance for No History Participants[a]

Variable	Adjusted Odds Ratio[b]	95% Confidence Interval	*P* Value

sionals, and extra resources can be directed to referral follow-up.

The results suggest that the influence of the behavioral interventions depends on cholesterol history and communicator type. For those with newly identified elevations, both types of follow-up yielded better physician visit rates than no follow-up. Although the rates were higher than found in studies without follow-up only for previously diagnosed subjects, direct comparisons are limited since these reports are not adjusted for prior awareness and rely on small samples with low response rates.[5,6]

The higher compliance rates for the coupon intervention contribute to the promising use of material incentives in other coronary heart disease risk programs.[20–22] However, questions of "how much" incentive is necessary and whether $17 in redeemable coupons for low-cholesterol foods would produce a similar effect in minority and lower socioeconomic populations need to be investigated. The reminder letter emphasized health beliefs associated with undertaking recommended health behaviors,[23] a more effective approach than reminder messages from a physician.[24] This may account for the lack of significant referral outcomes with the use of a physician follow-up letter by Lefebvre and colleagues.[25] The finding that communicator type may contribute to the success of reminders extends results on their effectiveness in cancer detection and influenza-vaccination programs[24,26] and hypertension screening follow-up.[27,28]

Since public screenings attract participants with a broad range of characteristics, it is encouraging that for no history subjects the follow-up interventions were more important than participant characteristics and attitudes in the adjusted analysis. The exceptions were risk level and behavioral intention (predictive of health behavior in earlier studies),[29] suggesting inclusion of these issues in counseling and follow-up efforts. The equivocal effect of the reminder letter by communicator type is not supported by prior studies or motivational theory. Referral was based on age-specific cutpoints widely in use at the time of the screenings.[2] The present guidelines recommend referral at lower cholesterol levels (total serum cholesterol: 200 to 239 mg/dL) when two or more coronary heart disease risk factors other than high cholesterol are present.[3] It is not known whether our findings will apply equally at these lower levels, but the regression suggests that referrals at the new lower cutoffs may be less likely to seek retesting and diagnosis and would benefit even more from follow-up.

The logistic regression models should be interpreted with caution, as all model-selection methods are subject to error, and the reasonableness of assumptions can never be completely checked.[30] In a simple assessment of the predictive value of the final model by calculating the probability of a physician visit for each subject, comparison of the observed rates of compliance by no history subjects with the fitted estimates showed misclassification in only 12.8% of those seeking care ($P < .50$) and 17.7% of noncompliers ($P > .50$).

Although attrition between screening and follow-up was only 7% (and equally distributed among study groups), reanalyses of unadjusted results, conservatively considering "dropouts" to be "noncompliers," did not change the outcomes for no history subjects.

Barriers to screening follow-up due to enabling factors[31] did not occur (data not shown). Almost all referrals reported having a physician and health insurance or entitlement coverage, and no differences occurred in seeking medical follow-up by varying reimbursement for preventive services (e.g., private health plan, health maintenance organization, Medicaid). For unaware subjects, the most frequent reason for not seeking care was attributed to ability to self-manage high cholesterol (58.3%), and 45.8% of prior history subjects reported already being in treatment. Less than 6% of either group mentioned the lack of a physician, and treatment costs were a deterrent for less than 1%.

Investigation of referral compliance in the context of public screenings poses some limitations. Participants self-selected to attend and may have been more health conscious than the general Rochester population. The follow-up interventions might not produce similar incremental effects in programs where attendance stems less from individual initiative. Overestimation in rates due to physician visits for reasons unrelated to the referral may have occurred (e.g., some previously diagnosed individuals attended proximal to a scheduled "checkup" and 13% of nonreferred "usual" risk participants reported a post-screening visit), but the relative comparisons are valid in the context of the experimental design. Finally, although these findings cannot be generalized to minority populations, there are similarities to the Boston Model Systems Project, which had a higher proportion of minority attendance.[32]

The concern that public screenings will reach those already aware of their condition becomes increasingly important as more people report having had a cholesterol test (from 35% in 1983 to 65% in 1990).[14] Only 31% of aware participants were currently on a cholesterol-lowering regimen, suggesting that it may be beneficial to target those who have discontinued treatment to reinitiate appropriate medical care.

From a programmatic perspective, both types of follow-up interventions appear reasonably effective for newly identified participants. The reminder letter, with a cost of approximately $1.50 per subject for staff time and mailing, produced a similar percentage increase (18% adjusted) to the coupon offer but was only effective with lay communicators. Although the coupon offer resulted in generally better visit rates, the efforts and costs for redemption and distribution in relation to the 12% to 18% incremental effects should be considered.

Millions of individuals have been screened in public settings throughout the United States and will continue to attend these programs. The present study suggests some practical strategies to assist in linking referrals to medical care. □

Food Sources, Dietary Behavior, and the Saturated Fat Intake of Latino Children

Charles E. Basch, PhD, Steven Shea, MD, and Patricia Zybert, PhD

ABSTRACT

Background. Recent recommendations for Americans aged 2 and older call for a reduction in the average saturated fat intake to less than 10% of calories.

Methods. Using 24-hour dietary recalls collected from mothers of 4- to 7-year-old urban Latino children, we identified foods and dietary behavior patterns that distinguish children with higher and lower mean daily percentages of calories from saturated fat.

Results. Compared with children in the lowest quintile of intake, children in the highest quintile consumed more than twice as much saturated fat per day from high-fat milk products (18.5 g vs 7.8 g), mostly from whole milk. They did not consume different kinds of milk or different amounts of milk per eating occasion, but on average they consumed milk more frequently (2.8 vs 1.6 eating occasions per day). Even children in the lowest quintile, on average, exceeded the 10% of calories from saturated fat currently recommended. If low-fat (1% fat) milk had been substituted without other dietary changes, all but the highest two quintiles would have been within the recommended level.

Conclusions. The substitution of low-fat for whole milk appears to be a key strategy for preschool children for achieving recommended levels of saturated fat intake. (*Am J Public Health.* 1992;82:810–815)

Introduction

Numerous studies in adults link diet to risk of cardiovascular disease, some types of cancer, and other illness.[1–3] Dietary saturated fat in particular has been found to be associated with atherosclerosis.[2] Studies in young children[4–7] have found that total and saturated fat intakes are higher than recommended levels,[8–10] that saturated fat is associated with serum total and low-density lipoprotein cholesterol levels,[11] and that there is tracking of serum lipid[12] and nutrient intake levels.[6,13,14] One risk reduction objective for the year 2000, specified by the US Public Health Service (PHS)[10] and supported by the National Cholesterol Education Program (NCEP),[9] is to reduce average saturated fat intake among children aged 2 years and older from more than 13% to less than 10% of total calories.

We identified only two studies that examined the contributions of specific foods and food groups to young children's saturated fat intake.[4,15] The Nationwide Food Consumption Survey is a continuing national survey of food intakes by individuals that uses probability sampling and repeated dietary recall interviews of parents to provide surrogate reports of children's dietary intake. (For 1985, this survey included 222 children aged 1 to 3 and 149 children aged 4 to 5)[4] In this survey, milk products contributed almost 40% of children's saturated fat intake. In the Bogalusa study,[15] which used a single surrogate dietary recall interview per year, milk alone contributed more than 20% of saturated fat intake for children aged 3 (n = 106) and 4 (n = 219).

Conceptualization and measurement of diet can be addressed from multiple perspectives. Most nutritional epidemiology has examined the relationship between nutrient intake levels and disease or risk factors.[1–3] Several recent reports demonstrate the value of analyzing diet in terms of dietary behavior patterns, such as the amount and type of food eaten[16] and the frequency of eating throughout the day.[17] According to Willett,[18] educational interventions to assist the public in making healthful food choices should focus on specific foods and dietary patterns rather than on nutrients. To our knowledge, no published research has described the dietary patterns that determine children's saturated fat intake.

We sought to determine whether children with higher and lower saturated fat intakes eat different foods, or eat the same foods but have different dietary behavior patterns (i.e., do they eat different amounts per serving or eat the same serving sizes but eat more frequently). To do this, we collected 24-hour dietary recalls for young Latino children on seven occasions over 3 years. These data were used to determine the relative contributions of food sources to children's saturated fat intake, and to identify foods and dietary behavior patterns that distinguish children with higher and lower saturated fat intakes.

This paper was submitted to the Journal June 25, 1991, and accepted with revisions November 27, 1991.

Methods

Study Sample

Subjects were 4- to 7-year-old Latino children and their mothers living in northern Manhattan or the Bronx, New York City, and participating in the Columbia University Study of Childhood Activity and Nutrition. Ten percent of the mothers and more than 90% of the children for whom we had birthplace data (n = 204 mothers and n = 184 children) were born in the United States. Children were generally healthy, with no dietary prescriptions or restrictions. Recruitment, which was mainly from a pediatric practice of a large hospital in a disadvantaged urban community, is described in greater detail elsewhere.[11] All mother/child pairs who completed four 24-hour recalls from the first year of the study were included in the baseline analysis (n = 205 pairs; 103 male children). Of these pairs, 168 completed three 24-hour dietary recalls in the third year of the study as well. At the time of first recall, the children's mean age was 4.4 years (SD = 0.34) and the mother's mean age was 31.8 years (SD = 5.2). At the time of the fifth recall, the children's mean age was 6.3 years (SD = 0.42).

Data were elicited orally by trained interviewers from 1986 to 1989. Because Spanish was the language spoken at home by 95% (n = 195) of these families most of interviews were conducted in Spanish.

Measurements

During four fairly evenly spaced visits to our community field site in the first year and three visits in the third year of the study, each mother recalled her child's dietary intake during the previous 24 hours. After listing the foods eaten by her child during each eating occasion, she was then asked to describe portion sizes. A variety of probing techniques and adjuncts, such as three-dimensional food models, were used to enhance the completeness and accuracy of the mothers' reports. Dietary data were cleaned, coded, and edited by nutritionists prior to data entry and verification. Nutrient values were computed using the Georgetown University Study of Childhood Activity and Nutrition dietary analysis program.[19] Nutrient values for commonly eaten foods that were not included in the original database were added.[20–22] Previously reported data provide support for the reliability[6] and validity[11,23,24] of the mothers' reports of their children's diet.

Statistical Analysis

Typical nutrient intakes at two points in time were derived by averaging results from the four 24-hour recalls collected in year 1 (n = 205) and from the three recalls collected in year 3 (n = 168). Mean number of eating occasions, quantity, and grams of saturated fat from each food were calculated for each child. Foods were collapsed into 33 food groups (Appendix 1) based on a typology adapted from the US Department of Agriculture.[21]

Using data from year 1, a stepwise multiple regression analysis was used to select those foods that contributed the most to variance in percentage of calories from saturated fat. The possible independent variables were grams of saturated fat consumed per day from each of the 33 food groups. Grams of saturated fat for selected specific foods, most notably whole milk, were also examined.

Children were classified according to percentage of caloric intake from saturated fat and divided into quintiles. Joint classification analysis determined the stability of the quintile classification from year 1 to year 3.[25] More than 60% of the children who were classified in the highest (or lowest) quintile in year 1 remained in the highest (or lowest) two quintiles in year 3. Seasonal variation was not associated with saturated fat intake.

Stepwise discriminant analyses were used to select (1) those food groups whose grams of saturated fat per day and (2) those food groups whose number of servings per day most accurately distinguished children in the lowest and highest quintiles. The analysis by servings allowed us to identify foods both with and without fat that were associated with saturated fat intake. Prespecified serving sizes for each food were taken from the nutrient database (e.g., one cup of whole milk or one ounce of cheese = one serving). Multivariate analysis of variance was used to assess the overall significance of differences in the selected food groups across all five quintiles. Mean number of servings and mean number of grams of saturated fat per day were tested for univariate linear trends across the quintiles. The selected food groups were examined more closely to identify dietary behavior patterns, including specific foods mentioned, average amount consumed per eating occasion, number of eating occasions per day, and type of eating occasion (i.e., whether foods were consumed as part of snacks or main meals).

Data from year 3 were then used to verify the results. Mean percentage of calories from saturated fat was predicted using the food groups selected by the stepwise regression on year 1 data. The discriminant function generated from year 1 data was calculated using year 3 intakes and was used to classify subjects into extreme quintiles of percentage of calories from saturated fat in year 3.

All the analyses were replicated using calorie-adjusted saturated fat instead of percentage of calories from saturated fat. By using residuals from a regression with caloric intake as the independent variable and with saturated fat intake as the dependent variable, inferences can be drawn about saturated fat intake independent of total caloric intake.[3,25,26] Results were the same for calorie-adjusted saturated fat and nutrient densities. Only data for percentage of calories from saturated fat are reported because current recommendations are expressed in this way.[8–10]

Results

Data in Table 1 show that the reported mean percentage of calories from saturated fat in year 1 was 13.3% (SD = 2.2), approximately 30% higher than the amount of calories (less than 10%) recommended by the PHS.[9,10] Even children in the lowest quintile had an average reported consumption of more than 10% of total calories from saturated fat. High-fat milk products accounted for more than half and whole milk alone contributed 44% of the total reported saturated fat consumption across the sample.

Reported grams of saturated fat consumed per day from the following five food groups made the greatest successive incremental contributions to explained variance in the children's percentage of calories from saturated fat: high-fat milk products (R^2 = .56), beef/veal (R^2 = .60), enriched bread (R^2 = .62), animal fats/oils for cooking and table (R^2 = .65), and pork/lamb/sausage (R^2 = .67). Whole milk alone accounted for 41% of the variance.

Compared with children in the lowest quintile, children in the highest quintile consumed more than twice as much saturated fat per day from high-fat milk products (18.5g versus 7.8g), including more than twice as much from whole milk (13.2g vs 6.4g) and more than six times as much from hard cheese (3.4 vs 0.5g). The amounts of saturated fat from cheese were much smaller than those from whole milk.

TABLE 1—Daily Saturated Fat Intake from Selected Food Groups and All Foods, Calories from Saturated Fat, and Total Energy Intake by Quintile of Children's Percentage of Calories from Saturated Fat

	Lowest Quintile (n = 41)		Second Lowest Quintile (n = 41)		Middle Quintile (n = 41)		Second Highest Quintile (n = 41)		Highest Quintile (n = 41)		Total Sample (n = 205)	
	Mean	(SD)	Mean	(SD)	Mean	(SD)	Mean	(SD)	Mean	(SD)	Mean	(SD)

*$P < .05$ linear trend.
**$P < .01$ linear trend.
***$P < .001$ linear trend.

Parents of only four children in year 1 reported the consumption of low-fat or skim milk.

A discriminant function using grams of saturated fat per day from high-fat milk products and from beef/veal correctly classified 95% of the children in the two most extreme quintiles. A discriminant function using only grams of fat from whole milk correctly classified 84%. The multivariate analysis of variance showed significant overall differences among the five quintiles ($\Lambda = .43$, $P < .001$). Univariate tests for linear trends in grams of saturated fat from high-fat milk products and from beef/veal were both significant ($P < .001$ and $P < .01$, respectively).

A discriminant function using reported mean servings per day of high-fat milk products and of soda/punch/fruit drinks correctly classified 90% of the children in the two most extreme quintiles of percentage of calories from saturated fat. More reported servings per day of high-fat milk products and fewer servings per day of soda/punch/fruit drinks were associated with a high percentage of calories from saturated fat (Table 2). A discriminant function using only servings of whole milk correctly classified 84% of the children. The multivariate analysis of variance on number of servings per day indicated significant overall differences among the five quintiles ($\Lambda = .56$, $P < .001$). Univariate tests for linear trends in servings of high-fat milk products and of soda/punch/fruit drinks were both significant ($P < .001$) (Table 2).

Specific dietary behavior patterns involving whole milk were examined. In year 1, the mean number of servings per day ranged from 1.3 cups in the lowest quintile to 2.6 cups in the highest quintile (Table 2). The children in the lowest quintile did not consume smaller amounts of whole milk per eating occasion than those in the highest quintile (0.8 cups vs 0.9 cups) but consumed whole milk less frequently (1.6 vs 2.8 times per day). Overall, 56% of whole milk was consumed as part of snacks: 48% for children in the lowest quintile and 62% for children in the highest quintile. Thus, a substantial portion of whole milk was consumed daily as snacks, regardless of quintile membership.

Data from year 3 confirm the patterns observed in year 1. Grams of saturated fat consumed in year 3 from the five food groups selected using data from year 1 accounted for 58% of the variance in percentage of calories from saturated fat for year 3 data. The discriminant function from year 1 calculated using grams of saturated fat from year 3 correctly classified 79% of the children in the two most extreme quintiles in year 3. The multivariate analysis of variance on grams of saturated fat across quintiles was significant ($\Lambda = .58$, $P < .001$), but only the univariate trend for grams of saturated fat from high-fat milk products remained significant ($P < .001$). The discriminant function generated from year 1 data calculated with daily servings of high-fat milk products and soda/punch/fruit drinks in year 3 correctly classified 74% of the children in the two most extreme quintiles of percentage of calories from saturated fat in year 3 (Table 2). The multivariate analysis of variance on servings across quintiles was significant ($\Lambda = .74$, $P < .001$), but only the univariate linear trend for servings of high-fat milk products remained significant ($P < .001$). Although reported consumption of whole milk was lower in year 3 for all quintiles, children in the lowest quintile still consumed approximately half the number of cups per day as children in the highest quintile.

Discussion

The PHS[10] and the NCEP[9] recommend that children aged 2 years and older should consume less than 10% of their total calories as saturated fat. In our study, mean saturated fat consumption was 13.3% of total calories, and even children in our lowest quintile of saturated fat intake had reported an average consumption of more than 10%. Consistent with other studies,[4,15] we found that milk and milk products were the foods that made the greatest contribution to young children's saturated fat intake. Our data show that frequent consumption of whole milk was the single most important dietary be-

havior pattern that distinguished children with low and high saturated fat intake.

Substitution of 1% milk-fat milk for whole milk, without changing any other dietary behaviors, would have reduced the percentage of calories from saturated fat by 25% for the whole sample (from 13.3% to just under 10.0%) and by no less than 20% in any of the five quintiles. This single dietary substitution would have brought average intakes of all children but those in the two highest quintiles within the level recommended by the PHS[10] and the NCEP.[9]

Concerns have been raised about adverse effects of interventions to reduce children's fat intake,[27–29] but there are few data that empirically address how a moderately reduced fat diet affects growth or development. One study, based on a small sample of children (n = 40), reported growth failure in eight children associated with reduced caloric and zinc intake resulting from unsupervised dietary treatment of hypercholesterolemia.[29] Most research on the role of caloric intake in children's growth and development has been conducted in developing countries.[30–32] We did not identify any published population-based studies documenting adverse effects on growth or development resulting from a moderately reduced fat diet such as that recommended by the NCEP[9] or the PHS.[10] In our data, children in the lowest quintile of percentage of calories from saturated fat did not differ on average from children in any other quintile on measures of height, weight, body mass index, or sum of skinfolds.[33] (Methods for these measures are reported elsewhere).[34] A related issue is that selectively limiting foods that are high in fat, such as dairy products, may also restrict intake of protein and micronutrients.[27] However, given that low-fat, skim, and whole milk are equivalent sources of protein, carbohydrate, calcium, and most other micronutrients (Table 3), substituting low-fat for whole milk affects only intake of calories and fat. Moreover, balancing these concerns about possible unintended adverse effects of reducing children's calorie and fat intakes are national data showing that prevalence rates of obesity among children are increasing[35] and that many children eat too much saturated fat.[4–7]

Several limitations of this study must be considered. First, data in Table 2 show that the average number of servings of milk and milk products was lower in year 3 than in year 1. We have reported elsewhere that this decline is most likely an artifact of children entering school and mothers thus being unaware of their children's food consumption during lunch.[6] Because this change occurred in all five quintiles, it did not bias the results. Second, we defined saturated fat generically, but some reports indicate that different kinds of saturated fat affect serum cholesterol differently.[36,37] Although further research may lead to more specific recommendations, current dietary recommendations for children by the PHS[10] and the NCEP[9] are specified in these terms.

The generalizability of our findings may be limited because this study included a single sample of 4- to 7-year-old Latino children from low socioeconomic families in one disadvantaged urban community. The Latino population in disadvantaged urban settings is of particular interest for public health because it is growing rapidly[38] and because, compared with non-Hispanic Whites, Latinos have been shown to have increased prevalence of some cardiovascular disease risk factors,[39–44] to have lower levels of knowledge about cardiovascular disease risk factors,[39,44] and to consume more saturated fat and less low-fat and non-fat milk than other ethnic groups.[45,46] Generalizability may also be limited because our data were collected from 1986 to 1989. Over the last two decades, national per capita consumption of whole milk has declined while consumption of low-fat milk has increased,[47] yet less than 4% of the

parents of the children in our sample reported consumption of low-fat or skim milk. While our data suggest no substantial shift to low-fat milk, we cannot be sure that this change has not occurred since 1989.

The gap between national estimates showing that 4- to 5-year-old children consume an average of 14.7% of calories from saturated fat[4] and recommendations by the PHS[10] and the NCEP[9] that children aged 2 years and older should consume less than 10% of calories from saturated fat indicates a need for many young children to modify their typical diet. We conclude that, for those young children who consume more than 10% of calories from saturated fat and whose family and pediatrician have decided to pursue dietary change to reach national dietary recommendations,[9,10] an important strategy is for parents to substitute low-fat milk for high-fat milk.[48] Maintenance of sufficient caloric intake should be part of any dietary recommendation. □

Socioeconomic Status and Health: How Education, Income, and Occupation Contribute to Risk Factors for Cardiovascular Disease

Marilyn A. Winkleby, PhD, Darius E. Jatulis, MS, Erica Frank, MD, MPH, and Stephen P. Fortmann, MD

ABSTRACT

Background. Socioeconomic status (SES) is usually measured by determining education, income, occupation, or a composite of these dimensions. Although education is the most commonly used measure of SES in epidemiological studies, no investigators in the United States have conducted an empirical analysis quantifying the relative impact of each separate dimension of SES on risk factors for disease.

Methods. Using data on 2380 participants from the Stanford Five-City Project (85% White, non-Hispanic), we examined the independent contribution of education, income, and occupation to a set of cardiovascular disease risk factors (cigarette smoking, systolic and diastolic blood pressure, and total and high-density lipoprotein cholesterol).

Results. The relationship between these SES measures and risk factors was strongest and most consistent for education, showing higher risk associated with lower levels of education. Using a forward selection model that allowed for inclusion of all three SES measures after adjustment for age and time of survey, education was the only measure that was significantly associated with the risk factors ($P < .05$).

Conclusion. If economics or time dictate that a single parameter of SES be chosen and if the research hypothesis does not dictate otherwise, higher education may be the best SES predictor of good health.(*Am J Public Health.* 1992;82:816–820)

Introduction

One of the strongest and most consistent predictors of a person's morbidity and mortality experience is that person's socioeconomic status (SES).[1–5] This finding persists across all diseases with few exceptions, continues throughout the entire life span,[5] and extends across numerous risk factors for disease.[6–9]

The significant impact of SES on disease makes its definition and measurement of critical importance. SES is a complex phenomenon predicted by a broad spectrum of variables that is often conceptualized as a combination of financial, occupational, and educational influences.[10–13] Although these dimensions of SES are interrelated, it has been proposed that each reflects somewhat different individual and societal forces associated with health and disease. For example, income reflects spending power, housing, diet, and medical care; occupation measures prestige, responsibility, physical activity, and work exposures; and education indicates skills requisite for acquiring positive social, psychological, and economic resources.[9,14]

Much has been written about the underlying mechanisms through which SES may operate to affect disease. Many authors have suggested that certain dimensions of SES are more predictive of health than others;[1,14–16] however, such proposals tend to be theoretically based, without substantiating data. Over time, education has become the most commonly used measure of SES in epidemiological studies,[17] yet no investigators in the United States have conducted an empirical analysis quantifying the relative contributions of different measures of SES to risk factors or disease outcomes. (This paper does not suggest which component of SES may be the most reliable and valid measure because this question has been examined, with a variety of conclusions, in previously published reports.)[10–13, 17–18]

The present study examines the association between income, education, occupation, and a set of risk factors for cardiovascular disease—namely, cigarette smoking, systolic and diastolic blood pressure, and total and high-density lipoprotein (HDL) cholesterol. Our study objectives are to (1) examine the impact of each separate dimension of SES on cardiovascular risk factors, (2) use a forward stepwise selection model to evaluate if one measure of SES is the strongest predictor of risk factors, and (3) offer guidance to researchers about selection of SES measures. This guidance is critical because nearly all epidemiological studies use SES as an explanatory or a control variable, or for the selection of subjects or matching criteria.

Methods

Subjects aged 25 to 64 were drawn from the two control cities of the Stanford Five-City Project,[19] a communitywide cardiovascular disease intervention study that contains data from four separate

Editor's Note. See related editorial on p 785 of this issue.

cross-sectional surveys, conducted from 1979 to 1986. Participants who were unemployed (n = 98), students (n = 130), or retirees (n = 146) were excluded because they had no occupation that could be ranked. Data from the four cross-sectional surveys were pooled because demographic characteristics, including measures of SES, showed no significant interactions over time.[7] As previously reported,[20] the educational attainment of respondents from the control cities were well matched to those from the treatment cities. A nonrespondent questionnaire indicated that participants were generally more educated than those in both treatment and control communities who refused to participate.[20]

Information on education, income, and occupation was ascertained through questionnaires. Education was recorded as the highest number of years of schooling completed. It was used as a continuous variable in regression analyses and was divided into the following four categories in stratified analyses: less than 12 years, 12 years, 13 to 15 years, and 16 years or more.

Income information, defined as gross annual household income, was collected in intervals of $5000. For multivariate analyses, the midpoint of the income categories was used; for the remaining analyses, income was divided into five categories ranging from less than $10 000 to $40 000 or more per year.

Current occupation was collected as an open-ended variable and coded using the 1980 US Bureau of the Census occupational scaling system, which creates a hierarchy of occupations ordered on the basis of education and income.[21] To examine associations between separate occupations and risk factors, we coded each occupation, including homemaker, as an indicator variable, with executives as the reference category. In multivariate models, we excluded homemakers and used occupation as a ranked variable ranging from executives to unskilled workers.

Participants were considered cigarette smokers if they reported ever smoking on a daily basis and had smoked one or more cigarettes in the last week. Participants whose plasma thiocyanate exceeded 100 μmol/L and whose expired-air carbon monoxide level exceeded 8 ppm were classified as smokers regardless of their self-reported responses.[22] Total and HDL plasma cholesterol were derived from nonfasting venous samples, analyzed fresh by standard methods established by the Lipid Research Clinics Program.[23] Three blood pressure measurements were taken on the right arm using a semiautomatic recorder, and the average of the second and third readings were used for analyses.[24]

Results

An overall response rate of 69% was achieved. Approximately 600 individuals participated in each survey, resulting in a total of 2380 participants for all surveys combined. Because the study population was predominantly White, non-Hispanic (85%), findings are not generalizable to populations representing a broad spectrum of racial groups.

All pairwise correlations between education, income, and occupation were positive and were stronger for men than for women (Table 1). The lowest correlation was between education and income, indicating that education is not a primary determinant of wage. Higher correlations were shown for education and occupation, suggesting that skills acquired during education may help determine occupation. Although correlations ranged from .23 to .67, their relatively low magnitude (highest adjusted R^2 = 45%) indicates that the three dimensions are not redundant measures of SES.

Although the study population had relatively high educational and financial levels, individuals from all education, income, and occupation categories were well-represented (Table 2). However, while men were represented fairly evenly across occupations, approximately 75% of women employed outside the home held nonprofessional white-collar jobs. Men tended to have more years of education than women and to be from higher-income households.

TABLE 1—Correlation Coefficients for Education, Income, and Occupation

	Men	Women
Education/income	+.32	+.23
Income/occupation	+.41	+.30
Education/occupation	+.67	+.66

Note. Table excludes homemakers. All correlations are significant at $P \leq .0001$.

In general, those with the lowest educational attainment exhibited the highest prevalence of risk factors (Table 3). Clear gradients were seen between educational level and smoking for both sexes, and between education and total and HDL cholesterol for women. Across all risk factors, men consistently exhibited higher risk than did women.

Income and occupation were less consistent risk predictors. Higher risk was associated with lower incomes for smoking and HDL cholesterol in both sexes but with higher incomes for total cholesterol in men. Within occupations, men and women white-collar executives and managers exhibited the lowest levels of smoking. Among men, executives and managers showed the lowest mean levels of blood pressure.

To compare the strength of the interrelationships between the three dimensions of SES, we conducted regression analyses (Table 4), adjusted for age and time of survey. Partial correlations are presented with two-tailed *P* values, with significance defined as $P < .05$. The univariate relationship between SES and risk factors was strongest and most consistent for education, showing higher risk associated with lower levels of education. Using a forward selection model that allowed for inclusion of all three measures of SES after adjustment for age and time of survey, education was the only measure of SES that was significantly associated with the risk factors. This finding is consistent with a previously conducted multivariate analysis, which showed that the strength and significance of the associations between education and a set of disease risk factors remained virtually unchanged after adjustment for income and occupation.[7]

When stratified by White, non-Hispanic and Hispanic ethnicities (not shown), education remained the strongest SES predictor but became nonsignificant for smoking, possibly because of the small sample of Hispanics.

Discussion

Strengths and Limitations of Using Education as the Marker for SES

We caution that, in some studies, using only one indicator of SES may yield misleading results or provide less information than using multiple measures. However, using multiple or composite measures[10–14] requires the cost and time of collecting data on several SES parameters and may not significantly explain more about a population than would a single, well-chosen parameter. As noted by a re-

cent working group of the National Heart, Lung, and Blood Institute, use of composite measures may obscure important differences in associations.[25]

Based on our findings, education may be the most judicious SES measure for use in epidemiological studies (unless the study hypothesis dictates which dimension of SES is to be chosen). In studies that have a cost or time restraint but need a measure of SES as a potential confounding variable, education is an expeditious choice. In addition, education is available for all individuals regardless of employment status, has high reliability and validity,[17] is generally stable after early adulthood, is easily reported, and can be collected as a continuous variable. Furthermore, because education is often available in epidemiological studies,[17] it also permits opportunities for meta-analyses and interstudy comparisons.

However, there are potential limitations to using education as a sole indicator of SES. Its stability can mask important changes in individuals' circumstances. There may also be a cohort effect distorting differences between populations of various ages. For example, the percent of the population obtaining at least a high school education has increased nearly threefold since 1940.[17] This has led to increasing homogeneity in the amount of education obtained, making differentiation between educational strata more difficult. Other potential problems include regional differences in education, the question of whether degrees or certification are better measurement parameters than years of schooling,[17,26,27] and the possibility that other dimensions of SES are more sensitive markers for health in some population subgroups. (For example, for foreign-born female Hispanics, acculturation may be a stronger measure of SES.)[13]

Comparison with Past Studies

To our knowledge, this is the only study in the United States to examine associations between separate SES dimensions and risk factors or disease outcomes. Other studies, however, have examined associations between one measure of SES and one disease risk factor,[6,8,28–32] morbidity,[33] or mortality.[1,33–35] In general, these studies have found that education is more strongly associated with disease than is income or occupation. One of the most complete studies of mortality differentials found that lower SES groups exhibited higher rates of all-cause mortality than did higher SES groups, irrespective of whether education, income, or occupation was used as the measure of SES.[1] Other studies have documented strong inverse associations between education and all-cause mortality[31,34,36] and life expectancy.[37] Framingham study data shows that, of 23 potential contributors to morbidity, only education and age at study enrollment were related in both sexes to "survival with good function."[38] Cardiovascular disease studies have shown that lower levels of education are associated with hypertension,[6,28–29,31,39] cigarette smoking,[6,31,32,40–41] and high cholesterol,[6,32] as well as with cardiovascular morbidity[33] and mortality.[31,33,35]

Why Education May Be the Strongest Predictor of Good Health

Several different mechanisms through which education may positively influence health have been proposed. Fuchs has suggested that both education and health are markers for willingness to delay gratification in order to "invest in human capital."[15] Others have argued that education may simply serve as a marker for intelligence; however, studies showing that environmental factors are the strongest predictors of school dropout lend little support to this hypothesis.[42] Some have suggested that higher education may improve health by conferring economic advantages, but our low correlation coefficients between education and income, as well as the lack of significant income effects on risk factors, argue against this hypothesis. Neither does the health knowledge acquisition that accompanies higher education appear to explain the relationship between education and health, given that provision of information alone appears to be a weak stimulus to human behavior change.[16,37]

One hypothesis we find most plausible is that education may protect against disease by influencing life-style behaviors, problem-solving abilities, and values.[17] Moreover, education may facilitate the acquisition of positive social, psychological, and economic skills and assets, and may provide insulation from adverse influences.[7] Such skills and assets that may accompany higher educational attainment include positive attitudes about health, access to preventive health services,[15] membership in peer groups that promote the adoption or continuation of positive health behaviors, and higher self-esteem and self-efficacy.[43,44]

Summary

There can be no SES measure that is universally valid and suitable for all populations. However, if economics and time dictate that a single parameter be chosen and if the research hypothesis does not dictate otherwise, this study suggests that higher education, rather than income or occupation, may be the strongest and most consistent predictor of good health. □

Socioeconomic and Behavioral Correlates of Body Mass Index in Black Adults: The Pitt County Study

Janet B. Croft, PhD, David S. Strogatz, PhD, Sherman A. James, PhD, Nora L. Keenan, MPH, Alice S. Ammerman, DrPH, Ann M. Malarcher, PhD, and Pamela S. Haines, DrPH

ABSTRACT

Background. Obesity is more prevalent among Black women than Black men, but there is little information on the correlates of obesity in Blacks. This study describes the relations of sociodemographic factors and health behaviors to body mass index in a southern, Black population.

Methods. In 1988, a community probability sample of 1784 Black adults, aged 25 to 50, was examined in Pitt County, NC.

Results. More women than men were at least 20% overweight (57% vs 36%). The relation of socioeconomic status (a composite of education and occupation) to age-adjusted body mass index level was inverse in women but not in men. Body mass index did not differ with either current energy intake or energy expenditure. Smokers and drinkers had lower age-adjusted levels than nonsmokers and abstainers.

Conclusions. Since the excess body mass index levels associated with low socioeconomic status in women could not be explained after controlling for adverse health behaviors, further epidemiologic study of risk factors for obesity in Black women is recommended. (*Am J Public Health.* 1992;82:821–826)

Introduction

A recent National Institutes of Health consensus development conference emphasized the need for epidemiologic research on the distribution and etiology of obesity in minority and lower socioeconomic populations.[1,2] Obesity, or excess adiposity, is a major health problem in the United States, with over 34 million overweight adults (25.7%) defined as at least 20% over their desirable weight.[3] Among Black women, the prevalence is much higher, with 43.8% overweight and 19.3% severely overweight (at least 40% over their desirable weight).[3] Considering that Black women have twice the overweight prevalence of White women, it is not surprising that Black–White comparisons of US mortality rates and morbidity prevalence suggest an excess of obesity-related health outcomes among Black women.[4] This excess calls for more extensive investigations of potential environmental and behavioral risk factors of obesity in this group.

Socioeconomic status (SES) is an important correlate of obesity level in US populations.[5–9] Body mass index (BMI) level, skinfold measurements, and overweight prevalence in Black women have consistent inverse relationships to SES indicators, including educational level, poverty status, and income level.[7,10] A weaker positive relationship between SES and BMI has been observed in Black men.[8–11] SES probably reflects broad environmental exposures as well as specific behavior patterns. The association of low SES with increased use of alcohol and cigarette smoking,[12,13] increased unemployment,[13] and a higher caloric intake[14] has been observed in the economically heterogeneous adult Black population of Pitt County, NC. Literature reviews suggest inverse relationships of both cigarette smoking and alcohol use with obesity in men and women.[4,15,16] Although obesity is assumed to be a consequence of the chronic imbalance between energy intake and expenditure,[17] a review of obesity in Black women suggested that excess obesity may not be related to excess caloric intake.[4] This study provides an opportunity to further examine the relationship of these health behaviors to BMI, a surrogate measure of obesity, and to examine whether the association of SES with BMI can be explained by these life-style behaviors.

Editor's Note. See related editorial on p 785 of this issue.

Methods

The overall purpose of the Pitt County Study is to determine psychosocial and dietary risk factors for elevated blood pressure in an eastern North Carolina population of young and early-middle-aged Black adults. In 1988, a stratified random sample of all dwellings within Pitt County (33% Black, 66% White) was used to select a community probability sample of 25- to 50-year-old Black adults. Selection of the probability sample has been described elsewhere.[12] Among the 2225 age-eligible Black residents, interviews were obtained throughout the year in the homes of 1784 (80%) adults.

After the respondents removed shoes and heavy clothing, trained interviewers obtained measurements of weight (in pounds) with a Healthometer portable scale and height (to the nearest inch) with a vertical ruler. BMI was computed as weight in kilograms divided by a squared term of height in meters. Three BMI categories were created using the 1983 Metropolitan Life Insurance Company relative weight tables[2,10,18,19] as a standard. There were no reliability assessments of height and weight measurements.

A standardized questionnaire was completed by each participant during the interview and included questions on health habits, education, occupation, and food frequency. Detailed descriptions of questionnaire components are provided elsewhere.[12–14,20] The food frequency component[21] was modified to reflect regional food practices and was administered as part of the interview to obtain estimates of daily intakes of nutrients and total calories (an indicator of energy intake).[14] Alcohol consumption was divided into four categories, ranging from abstention to seven or more drinks per week.[12] Other health habits included current cigarette smoking and physical activity. Strenuous physical activity (a general indicator of energy expenditure) was based on self-reports of sweat-producing work or exercise lasting for 20 minutes or more, at least three times a week.[20,22] Participants were defined as married if they reported either being married or living with a companion. Individuals who had previously worked but were not working at the time of the interview were characterized as currently unemployed; currently employed persons, homemakers, students, and individuals who had never worked were characterized as "other." An SES index combining education and occupational status was developed.[13,14] The low SES category included unskilled workers who had a high school education or less and semiskilled workers who had not completed high school. The intermediate SES category included unskilled workers who had education beyond the high school level, semiskilled workers who had at least completed high school, and participants who had not finished high school but reported skilled craftsman or white-collar occupations. High SES classified those who had a high school education or greater and reported skilled craftsman or white-collar occupations.

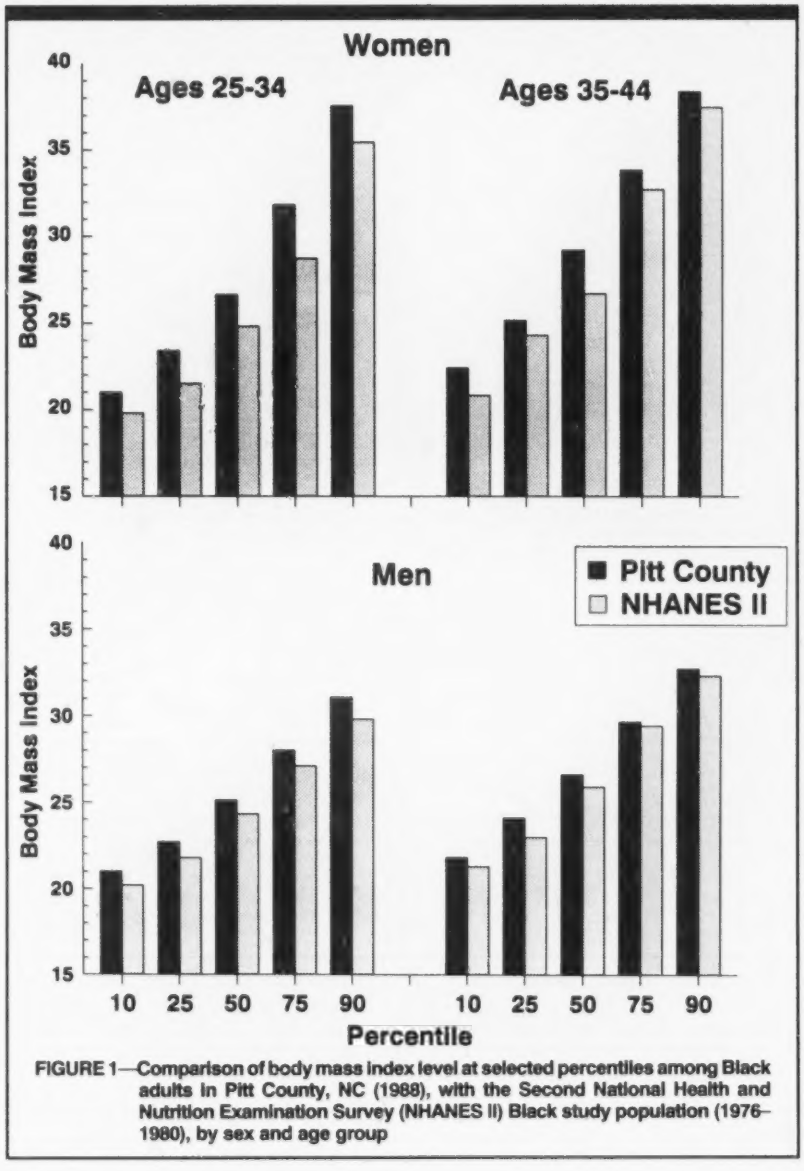

FIGURE 1—Comparison of body mass index level at selected percentiles among Black adults in Pitt County, NC (1988), with the Second National Health and Nutrition Examination Survey (NHANES II) Black study population (1976–1980), by sex and age group

Individuals missing values for height, weight, relevant health behaviors, or SES were not included in the final analyses, resulting in a total of 1663 (93%) individuals with complete data. All analyses were sex specific and weighted to take into account the sampling strategy as well as nonresponse. Sex-specific distributions of categories of BMI, sociodemographic characteristics, and health behaviors were obtained to describe the study population. Age-adjusted mean BMI and the difference in mean BMI level between categories of each potential correlate were obtained with age-adjusted linear regression techniques. The 95% confidence interval for each difference was computed using standard errors obtained with SUREGR.[23] Multivariable linear regression techniques with BMI as the dependent

variable were used to assess correlates of BMI. Product terms combining smoking status and specific levels of alcohol consumption were added to the multivariable model to assess whether there was an interactive effect of alcohol and tobacco use on BMI level.[16] In a separate analysis, a product term combining exercise level and caloric intake was added to examine whether the relation of energy intake to BMI level varied with level of energy expenditure.

Results

The sample included 633 Black men and 1030 Black women. BMI levels ranged from 15.7 to 58.7 kg/m^2 (mean = 29.4) in women and from 16.99 to 46.3 kg/m^2 (mean = 26.3) in men. Figure 1 demonstrates that age-specific BMI levels in the Pitt County Black population were higher at selected percentiles than those of Blacks in the Second National Health and Nutrition Examination Survey (NHANES II).[3]

In all, 24.1% of women and 25.7% of men were classified in the 120% through 139% overweight category (Table 1). In comparison to 10.4% of men, an additional 33.3% of women were 140% or more overweight. Over 70% of the study population was under age 40. Men were more likely than women to be married and less likely to be currently unemployed. A greater proportion of women reported sedentary activity than men, while the proportion of women consuming less than 1500 calories per day was much higher than in men. In comparison to men, more women were nonsmokers and alcohol abstainers.

Mean BMI increased with age, especially in Black women (Table 2). Age-adjusted sex-specific associations of each correlate with BMI level were then examined (Table 2). Married individuals were heavier, especially among men. The mean BMI for low SES women was 1.5 kg/m^2 higher than for high SES women; however, BMI did not vary with SES level among men. Indicators of energy intake and energy expenditure were not associated with BMI level in women and men. Smokers had lower age-adjusted BMI levels than nonsmokers among both men and women. Women who consumed alcohol were 2 to 3 kg/m^2 lighter than women who abstained, but there was no gradient with amount of drinks per week. However, among men, there was a monotonic decrease in BMI across the alcohol categories.

≥7	63	4.9	132	20.0

[a]Women with body mass index (BMI) levels of less than 26.9 kg/m^2 were included in the <120% overweight group; those with levels between 26.9 and 31.4 kg/m^2 were placed in the 120%–139% group; and those with levels of 31.4 kg/m^2 or more were placed in the ≥140% group. Men with BMI levels of less than 27.2 kg/m^2 were placed in the <120% overweight group; those with levels between 27.2 and 31.8 kg/m^2 were included in the 120%–139% group; and those with levels of 31.8 kg/m^2 or more were included in the ≥140% group.

Multivariable linear regression models were used to initially assess the association of sociodemographic variables to BMI level (Table 3, Model 1). Among women, age and low SES were the only independent sociodemographic correlates of BMI in this model. Marital status was the only independent sociodemographic correlate of BMI among men. The addition of health behaviors to these models (Model 2) did not account for the sociodemographic predictors identified in Model 1. Smoking and alcohol consumption were independent, negative correlates of BMI level among women, while only smoking behavior was an independent, negative correlate of BMI level in men. Similar results were obtained in separate models after using a continuous alcohol term and after substituting either the occupation or education component for the SES variable. Furthermore, there was no interaction of either smoking and alcohol consumption or physical activity and total caloric intake with BMI level in the multivariable models containing sociodemographic factors and health behaviors.

Discussion

The slightly higher BMI levels in the Pitt County population relative to NHANES II[3] could reflect a secular increase in levels since the 1976 to 1980 national survey. Secular changes in this direction have been described for young Black women between 1960 and 1980.[24] Alternatively, these data may reflect geographic differences in BMI, with more prevalent obesity and higher weight levels in the southeastern United States than in

other regions of the country.[25,26] Geographic differences in obesity prevalence would be consistent with regional differences in hypertension and hypertension-related mortality.[27,28]

The distributions of BMI, SES, and health behaviors, as well as the relation of sociodemographic and behavioral factors with BMI, differed between men and women in this economically heterogeneous sample of Black adults. Age was more strongly associated with BMI for women than for men. Childbearing may account for some of this difference in effect, since European studies suggest that some of the weight gained during pregnancy may be retained.[29,30] The enhanced association between age and BMI in women may reflect a cumulative impact of pregnancies.[31] Information on reproductive history was not available to examine this possibility.

Low SES was related to higher BMI levels in women but not in men. These relationships are consistent with those observed for surrogate measures of obesity in national surveys[3,7,8,10] and other cross-sectional surveys of Black populations.[9] Married men, but not women, were heavier than those who were unmarried. A predominantly White adult study reported a statistically significant and somewhat curvilinear relationship between marital status and BMI in both men and women, such that the lowest and highest BMI quintiles were less likely to be married.[32] Women at higher SES levels may be disproportionately more likely to be concerned with thinness and diet,[6] while there may be less social pressure for men to conform to an ideal body image. Furthermore, in the NHANES I follow-up cohort, the women at greatest risk of weight gain were those with low family income and less than a college education and those entering marriage.[33]

Ironically, more adverse health behaviors, cigarette and alcohol use, were negatively correlated with BMI in this study population and in others.[16] The finding that cigarette smokers had significantly lower BMI levels than nonsmokers is consistent with NHANES II data in which both male and female cigarette smokers were leaner than nonsmokers.[34] Several studies have reported a stronger inverse relation of alcohol with BMI level in women than men.[35–37] Differences between men and women in the relation of alcohol intake to BMI level might be explained, in part, by the decreased metabolism and gastric oxidation of ethanol in women.[38]

As in several surveys,[4,34,39,40] the present results demonstrated that on a population basis, excess body weight was not necessarily associated with higher caloric intake. A major problem of cross-sectional studies is that self-reported dietary intake may not reflect long-term dietary patterns or take into account individuals on weight-reduction diets. In the present study population, 8% of all men reported that they were currently dieting, regardless of overweight status; however, reports of dieting increased with overweight status among women (8%, 10%, and 17% in the < 120%, 120% through 139%, and ≥ 140% overweight categories, respectively). Multivariable linear regression results were similar after controlling for current dieting.

Although over 60% of women and 40% of men reported a sedentary lifestyle, sedentary behavior was also not related to BMI level in the Pitt County population. These results are not consistent with some studies that have observed an inverse relationship between physical activity and obesity level, especially in men.[35,39,41] The difference in results may be due to methodologic factors (e.g., the measurement and definition of physical activity, seasonal variations in sweat-producing activities, the sampling strategy, and criteria for inclusion in the study). Furthermore, cross-sectional surveys often do not measure long-term physical activity patterns and are unable to determine the temporal relationship of current physical activity with obesity level.

The results of this study confirm the empirical evidence that obesity is a prevalent problem among low SES populations and Black women. Low SES was an important correlate of high BMI in Black women, but elevated levels could not be explained by adverse health behaviors such as high caloric intake and sedentary activity. Furthermore, only a very small proportion of the variability in BMI in this population could be attributed to socio-demographic characteristics, smoking, alcohol use, and energy intake and expenditure. There is a need to quantify more precisely the effects of energy intake and expenditure on obesity levels in populations, to determine the temporal relationship between these life-style factors and the risk of developing obesity, and to identify and clarify the roles of genetic and other environmental factors (both behavioral and psychosocial) as risk factors, especially in low socioeconomic and minority subgroups. Such research must be conducted before effective public health interventions can be designed that target the special situation of low-income individuals, particularly women. □

Postgraduate Diabetes Symposium to Be Held in Fargo, North Dakota

"Diabetes, A Rural State's Perspective—Turning Obstacles into Opportunities" is the title of the 17th Annual Symposium for physicians and other health care professionals to be held Friday, November 6, 1992, at the Holiday Inn in Fargo, ND. This year's program is a collaborative effort involving many groups, all of whom are interested in providing postgraduate education. The sponsors include: the American Diabetes Association, North Dakota Affiliate, Inc.; the North Dakota Diabetes Control Program, State Department of Health; the Centers for Disease Control; the Indian Health Service; the University of North Dakota School of Medicine; and the Fargo Veterans Administration Center.

North Dakota ranks first in the nation in the incidence of diabetes per capita. In fact, the North Dakota diabetes death toll has reached its highest level in four decades, and the state is leading the nation in deaths per capita. Because of the state's rural setting, access and availability of health care presents serious issues for health professionals caring for persons with diabetes. Therefore, the symposium will focus on these areas and also on turning obstacles into opportunities.

The program features outstanding authorities on such subjects as type II diabetes management regimes, pregnancy and diabetes, access and availability of care, complication prevention strategy in rural settings, current and future research, treatment of type I diabetes on an outpatient basis, diabetic diet and rural access to nutrition, diabetes educators' role in rural diabetes, and North Dakota outreach programs.

The registration fees to attend the symposium are $25 for members and $35 for nonmembers. Students, residents, and interns may attend for $15. The fee includes lunch, a syllabus of the program, and other educational materials. The annual meeting and awards banquet of the American Diabetes Association will be held on Thursday evening, November 5, at the same location and is open to everyone.

For more information, contact Mary Ann Keller, RN, MS, CDE, Executive Director, at the American Diabetes Association, North Dakota Affiliate, Inc., 101 North Third St, Suite 400, Grand Forks, ND 58203; tel. (701) 746-4427 or toll free 1-800-666-6709.

Prevention of Cigarette Smoking through Mass Media Intervention and School Programs

Brian S. Flynn, ScD, John K. Worden, PhD, Roger H. Secker-Walker, MB, BChir, Gary J. Badger, MS, Berta M. Geller, EdD, and Michael C. Costanza, PhD

ABSTRACT

Objectives. In this study we tested the ability of mass media interventions to enhance the efficacy of school cigarette smoking prevention programs.

Methods. For 4 years, students in one pair of communities received media interventions and school programs that had common educational objectives. Students in a matched pair of communities received only the school programs. The combined cohort of 5458 students was surveyed at baseline in grades 4, 5, and 6 and was followed up annually for 4 years.

Results. Significant reductions in reported smoking, along with consistent effects on targeted mediating variables, were observed for the media-and-school group. For cigarettes per week the reduction was 41% (2.6 vs 4.4); for smoking cigarettes yesterday the reduction was 34% (8.6% vs 13.1%); and for smoking in the past week the reduction was 35% (12.8% vs 19.8%). No effects were observed for substance use behaviors not targeted by the interventions.

Conclusions. These results provide evidence that mass media interventions are effective in preventing cigarette smoking when they are carefully targeted at high-risk youths and share educational objectives with school programs. (*Am J Public Health.* 1992;82;827–834)

Introduction

Cigarette smoking prevention programs based in middle schools have consistently shown initial reductions in the proportion of students who begin regular smoking.[1] However, when students are followed up through grade 12 these effects have been lost.[2,3] Thus, these programs may have only delayed the onset of cigarette smoking. Strategies that could be used to broaden and extend the impact of these prevention programs include enhancing their effect by combining them with educational channels outside of the school setting.[4–6] This study was designed to test the additional effect that could be achieved by adding a mass media intervention to a school smoking prevention program.

Methods

Our hypothesis was that regular cigarette smoking would increase less among adolescents receiving a mass media intervention and a school smoking prevention program that had common educational objectives than among those receiving a school program only. Each treatment group included students from one community in the Northeastern United States and one community in Montana. Five annual in-school surveys were conducted in these four communities. The surveys were linked longitudinally.

Educational Interventions

On the basis of theory[7–12] and research on smoking initiation, we developed four common objectives for the educational interventions. As a result of these interventions, young people will have:

1. a more positive view of nonsmoking;
2. a more negative view of smoking;
3. improved skills for refusing cigarettes;
4. a better understanding that most people their age do not smoke cigarettes.

Our conceptual approach linked these objectives to mediating and outcome variables (Figure 1).[7,13] Additional common objectives concerning cessation skills and awareness of cigarette marketing to young people were added during the fourth year as a result of program development research.[14]

The mass media intervention consisted of radio and television spots designed to accomplish the objectives listed above. Six different producers developed 36 television and 17 radio spots, which were broadcast as paid ads over local media. About 15 different television spots and 8 different radio spots were broadcast during each of the 4 years.

Brian S. Flynn, John K. Worden, and Roger H. Secker-Walker are with the Office of Health Promotion Research and the Vermont Cancer Center; Gary J. Badger is with the Medical Biostatistics Unit; Berta M. Geller is with the Office of Health Promotion Research; and Michael C. Costanza is with the Medical Biostatistics Unit and the Vermont Cancer Center—all at the College of Medicine, University of Vermont, Burlington, Vt.

This paper was submitted to the Journal June 13, 1991, and accepted with revisions November 12, 1991.

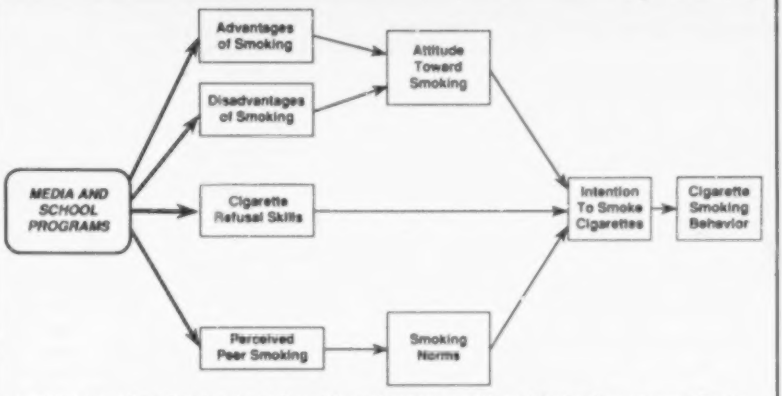

FIGURE 1—Hypothesized relationships of mass media and school program effects, mediating variables, and behavioral outcomes

The exposure plan for the first intervention year[14] was modified to match changes in media use as the target cohort matured. From the first to the fourth year, annual paid broadcast television exposures in each market were reduced from 284 to about 98; annual MTV and other cable television channel exposures were reduced from 450 to about 250; and annual paid radio exposures increased from 248 to about 450. In addition, we obtained approximately 50% further exposure from public service matching in all media. Placement of both paid and public service exposures in specific broadcast programs or viewing periods was guided by survey data.

To provide a uniform school smoking prevention program, we developed a program for grades 5 to 10 that included grade-specific curricular materials, annual teacher training, and monitoring of program implementation. The school program was based on the common educational objectives. Specific units emphasized decision making, skills to resist peer pressures and advertising pressures, social support for nonsmoking, and information about smoking and health. The curriculum was delivered by usual classroom teachers who were trained by project staff in four annual day-long teacher training workshops in each study community. For grades 5 to 8, the curriculum required four class periods per year; for grades 9 and 10, three periods were required.

The school program was linked with the media intervention only at the level of educational objectives. There was no direct programmatic relationship between the two because of the strategic decision to present the interventions as multiple, independent sources of information. The first school curriculum units were completed during the fall of 1985. The first year's television and radio campaign ran from January through May 1986; the campaign then continued at decreased intensity through the summer on radio only, with a short surge on both television and radio at the beginning of school in the fall. This pattern was repeated for 3 additional years. (Information about a videotape of selected media messages and about the school curriculum can be obtained from the authors.)

Study Sample

Two pairs of standard metropolitan statistical areas (SMSAs) were selected as best matches from regional pools. Selection criteria included being an independent media market; having a population between 50 000 and 400 000; and having matched demographic characteristics including education, income, and ethnicity. The regions were originally selected for demographic similarity to a Vermont SMSA.

One pair of SMSAs was located in the Northeastern United States (Vermont and south-central New York State) and the other was located in Montana (Table 1). Study samples were matched more closely through selection of specific school districts and feeder school units within these four SMSAs on the basis of demographic data from census tracts for the localities serving as catchment areas for the schools. Selection at this level focused on higher risk populations as indicated by adult educational attainment and household income. Initial consent to participate was obtained at the school-district level; no school refused. Within one community pair, the media-and-school community was so designated because of a need in the other community to avoid contaminating other health promotion studies within reach of the media. In the other community pair, the media-and-school community was so designated because its media served fewer outlying communities and broadcast costs were lower. A cohort of 5458 students from these four SMSAs was established in grades 4, 5, and 6 in the spring of 1985.

Measurement

Measures for each construct depicted in Figure 1 were included in each survey with the exception of refusal skills, which are difficult to measure effectively and efficiently in a questionnaire format. All measures were coded such that higher scores reflected increased levels of smoking behavior or risk.

The Smoking Behavior Index (SBI) consisted of three items that were weighted to the equivalent number of cigarettes smoked per week, then averaged.[15] The internal consistency reliability coefficient (Cronbach's alpha[16]) for this scale averaged .87 over five surveys. These self-reports were collected at the same time that a saliva sample was obtained. The students were told that the samples were taken to verify their self-reports; this procedure has been shown to enhance the validity of self-reports.[17]

"Intention to smoke" was measured by a single item. "Attitude toward smoking" was measured by a three-item scale[18] (α = .84). "Advantages of smoking" was measured by a seven-item scale[19] (α = .75). "Disadvantages of smoking" was measured by four items combined as an index. "Smoking norm" was measured by a three-item scale[20] (α = .72). "Perceived smoking by peers" was measured by a three-item scale (α = .70).

Measures of risk factors for smoking that were not targets of the intervention program were included to provide tests of the specificity of intervention effects.

Analysis

The results for the outcome measures are presented here in terms of means (proportions for dichotomous measures), with their 95% confidence intervals, for the subset of participants who took part in all five school surveys. The unit of analysis for these presentations is the individual, according to the original design of the experiment. A supplemental analysis is presented in which the community is the unit, although the original design was not intended to support this analytic strategy.

Results

Less than one percent of the parents requested that their children not take part, and nearly all absentees were surveyed through later visits to schools. In this report we focus on the students who participated in all four additional surveys. Forty-seven percent (2540) of the cohort was present for all surveys (50% in the school-and-media group and 43% in the school-only group). Of those not included in the five-survey study sample, 82% moved out of the community or transferred to private schools, 15% missed one or more intermediate surveys, and the remainder were refusals, nearly all from one district that changed its consent procedures midway through the study.

Comparison with Other Baseline Participants

To assess differences between those who participated in all five surveys and the 2918 who did not, we compared baseline characteristics. Students in the five-survey sample were slightly younger (10.7 vs 10.9 years; $P = .001$) and included more girls (49.6% vs 46.4%; $P = .02$). They reported less smoking among family members, with fewer reporting any older brothers who smoked (13.8% vs 21.0%; $P < .001$), any older sisters who smoked (14.7% vs 24.9%; $P < .001$), and smoking by either parent (53.2% vs 65.3%; $P < .001$). These students also reported less smoking behavior than did those in the other group, as measured by the SBI (0.06 vs 0.53 cigarettes per week; $P < .001$), smoking yesterday (0.6% vs 3.0%; $P < .001$), and smoking in the past week (1.4% vs 5.6%; $P < .001$).

Baseline Equivalence of Treatment Groups

We compared the characteristics of those completing five surveys in the school-and-media group and in the school-only group. The school-and-media group was slightly younger (10.7 years vs 10.8 years; $P = .002$) and included more females (51.8% vs 47.0%; $P = .02$). The school-and-media group was somewhat more likely to report having an older brother who smoked (15.8% vs 11.3%; $P = .06$), but there were no other differences in family smoking. Measures of behavioral and psychosocial impact were examined to assess baseline equivalence. None of these characteristics differed significantly for the two groups, except that the school-only group reported perceiving more peer smoking (see Year 1 data in Table 2).

Impact on Cigarette Smoking Behaviors

Figure 2 depicts the SBI with 95% confidence intervals for the two study groups over 5 years. These data show a consistent trend toward less smoking by the school-and-media group, with significant differences appearing in the final 2 years. In the fifth year the school-and-media group reported smoking an average of 2.6 cigarettes per week, compared with 4.4 cigarettes per week for the school-only group, a relative difference of 41%. SBI measures for each of the four study communities are shown in Figure 3; the smoking patterns were similar within each pair of study communities. Examination of responses to individual items in this scale, indicating whether the respondent smoked any cigarettes yesterday or in the past week, showed similar patterns (Table 3). In the fifth year, smoking yesterday was reported by 8.6% of the school-and-media group and 13.1% of the school-only group, a relative difference of 34%; the percentages reporting smoking in the past week were 12.8% and 19.8%, respectively, a relative difference of 35%.

As an alternate approach to assessment of smoking behavior changes, a repeated measures analysis of variance was done using the community as the unit of analysis and blocking on geographic area (east, west). This analysis showed a significant difference between treatment groups in the trends observed over time for the SBI scores ($P < .01$).

Impact on Targeted Mediating Variables

The impact of the interventions on hypothesized mediating variables (see Figure 1) is shown in Figure 4 and Table 2. The pattern was similar for each measure. The groups were equivalent at baseline, then showed a significant difference in the second year, which persisted through the fifth year. Results from each community for three key mediating variables (Table 4) indicated similar patterns of effect within each community pair.

Impact on Variables that Were Not Targeted

Use of two substances not targeted by the interventions, smokeless tobacco and alcohol, was measured in each survey (Table 5). In smokeless tobacco behavior, reported as any use in the past week, the two groups did not differ significantly except in the fourth year, when the school-only group was more likely to report use. The groups showed no difference in alcohol use (having had beer more than once)

TABLE 2—Mean Scores for Mediating Variables Targeted by Interventions Over 5 Years, with 95% Confidence Limits

until higher levels of use were observed among the school-only group in the fifth year. The groups did not differ over 5 years on a psychosocial stress scale, and differed in perceived adult smoking only in year 3.

Recall of Exposure to the School Program

Items measuring recall of grade-specific elements of the school curriculum were included in the surveys for years 2 to 5. Scores were added and converted to percentages of elements recalled (Table 6). Three of the four communities produced index scores that were generally in the same range. The fourth community had somewhat lower scores.

Discussion

Consistent patterns of effect favoring the school-and-media group were found for smoking behaviors and mediators of these behaviors that were targeted by the educational interventions. Behavioral and mediating variables not targeted by the interventions generally failed to show any

trend for higher levels of risk in the school-only group. Thus, the interventions appeared to have consistent effects only on those variables it had targeted, which suggests that the effects were independent of any possible underlying general differences in study group characteristics.

The consistency of the impact of the program also can be seen clearly for smoking behavior when the two pairs of communities were viewed as four separate communities (Figure 3). The two school-and-media communities showed a clear separation from the two school-only communities in the third through the fifth surveys. Similar patterns are also seen in the data from all four communities for mediating variables (Table 4). These data also tend to support the conclusion that the effects observed were due to the interventions.

Further evidence for the internal consistency of these results can be seen by comparing the temporal ordering of the appearance of differences among the various targeted variables. In keeping with theoretical expectations, differences generally appear sooner in mediating variables (Figure 4 and Table 2) and later in smoking behavior variables (Figure 2 and Table 3).

The media-and-school group was slightly younger than the school-only group and contained a larger proportion of females. Younger age and greater female representation may offset one another as risk factors for adoption of cigarette smoking. Beginning at about grade 8, girls in this study were more likely to report that they were smokers. Separate analyses done within gender and grade-level categories (not shown here) showed patterns of effect similar to those seen in the aggregated data. Baseline comparisons of behavioral and psychosocial variables showed no differences (Table 2) except for perceived peer smoking. This difference was likely due to the slightly older age and greater male representation in the school-only group. Males were more likely to report smoking in the younger grade levels surveyed at baseline.

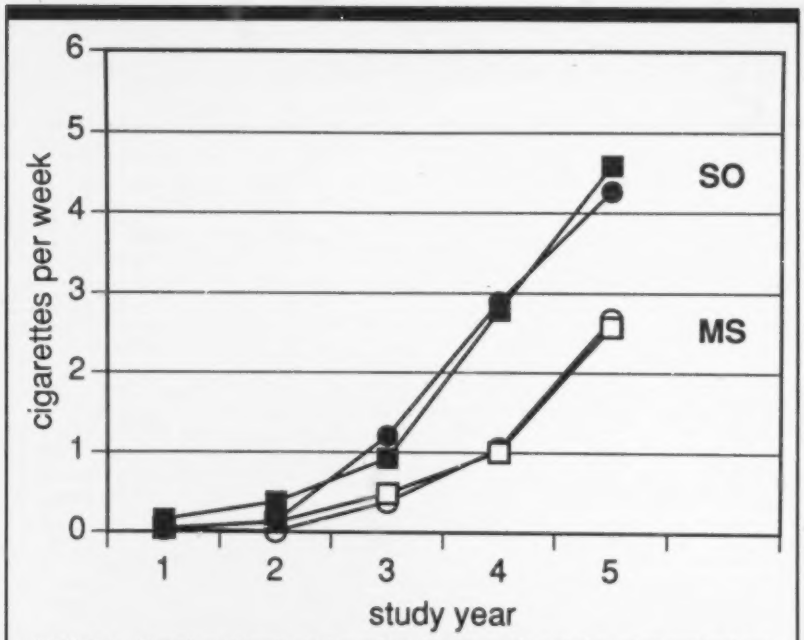

FIGURE 3—Smoking Behavior Index values (mean number of cigarettes smoked per week), by four individual study communities. The school-only communities (SO) are indicated by filled symbols and the Northeastern communities are indicated by square symbols

With respect to the school program, it should be noted that its length, starting point, and content rank it as a relatively intensive smoking prevention intervention.[1] Although differences among communities in levels of school program exposure were reported, these differences were small in relation to the differences observed in smoking behavior. Differences in reported exposure generally did not coincide with changes in smoking behavior (Figure 3 and Table 6) or mediating variables (Figure 4 and Table 4); this is especially apparent when data for the two school-only communities are compared. It is possible that these differences in level of implementation had little or no effect on smoking behavior because the lowest level of reported school program implementation exceeded a ceiling above which no further effect could have been attained.[1,4,21,22]

The study was designed with individual participants as the unit of analysis. However, because of the need to apply the educational programs to larger aggregates rather than to randomly selected individuals, participants were allocated to treatment conditions by communities. We have carried out the analyses according to the original design, using individuals as the primary analytic unit. An additional analysis was conducted with the community as the analytic unit, although the original design did not anticipate this approach. This supplementary analysis produced results similar to those of the main analysis, providing confirmation at the community level of the impact of the mass media intervention.

The results reported in this paper were for students who participated in all surveys. Most of the other students left the school systems after the first survey. Very few parents or students refused to participate in any survey, and nearly all absentees at the time of the main surveys were subsequently surveyed. It seems likely that those excluded from these analyses live in less stable family environments; this likelihood reduces the generalizability of these results for a part of the adolescent population that is at somewhat higher risk for adoption of smoking.[23] We are following up the entire cohort to assess the sustained impact of the program.

A second factor that limits the generalizability of the study is the lack of racial and ethnic diversity in the study population. This feature of the study is a result of a matching process that began in a relatively homogeneous area. The challenge for researchers is to adapt the strategies used here to devise equally effective campaigns for other major population groups and for more heterogeneous populations.

Interpretation of Mass Media Effect

Aside from the fact that it shared common objectives with a school program, the impact of this mass media intervention may be attributed to several features that set it apart from previous efforts using mass media in health promotion[12,14]: the intervention had sufficient duration; it used multiple channels; it was presented at times and places when young people reported their highest use of media; it used a variety of message styles; it used appeals to age- and gender-specific motives determined through surveys and focus groups; and it used messages portraying perceived social support with attractive age- and gender-relevant models providing appropriate behavioral skills, alternatives, and reinforcement.

This intervention also avoided the use of exhortations; the spokespersons were credible young models saying "I don't smoke," letting each youngster make his or her own decision. Program formats that appealed to young people were used for these messages: situation comedies, cartoons, rock videos, and testimonials. Because young people at higher risk for smoking also tend to shun authority, the messages were not "tagged" with a logo or name of a sponsoring agency; the sponsor was identified only in an unobtrusive copyright notice. Lastly, rather than presenting only a few spots in each "flight" (6- to 15-week period) in an effort to ensure awareness of specific content, we presented 12 to 18 different spots in each flight to establish a perception of a nonsmoking lifestyle; more popular spots were repeated annually.

It is important to underscore the role that the media play in the socialization of

young people. Television has been considered to be a major agent of socialization through which children learn the definitions and expectations underlying the rules and norms of their culture.[24] Parents and teachers witness this process every day as new trends seen in the media become the new behaviors to be adopted in the real world. Because the messages used in this intervention had no unifying tag or logo, and because they appeared to come from many sources simultaneously, it is possible that the young people in our intervention communities thought that these messages were being received by young people across the nation and perceived them as redefining norms for youth smoking.

Other Mass Media and Smoking Prevention Studies

The present study is one of three research projects that were funded by the National Cancer Institute in 1984 to evaluate mass media smoking prevention approaches. The others involved school and family participation with evening newscast coverage[25] and television and radio spot messages with sweepstakes participation.[26] Bauman et al.[27] reported that the media-sweepstakes program produced changes in some mediating variables.

TABLE 6—Mean School Program Exposure Index Scores (Percentages) from All Four Communities

	Year				
Community	2	3	4	5	n
MS (NE)	80.4	84.4	69.2	67.0	811
SO (NE)	76.5	80.1	69.3	58.9	480
MS (M)	79.2	81.6	65.0	66.2	516
SO (M)	69.3	76.9	49.4	49.1	610

Note. MS = media-and-school; SO = school-only; M = Montana; NE = Northeastern.

A media and school-based campaign conducted in Australia, in which an uncontrolled evaluation design was used, resulted in reductions in adolescent smoking.[28] Pentz et al. reported the impact on adolescent smoking of a multicomponent prevention program,[29] but mass media effects were not assessed independently. These two apparently successful programs combined mass media with school programs and other channels of influence for young people. They provide additional evidence that carefully targeted mass media interventions can have a favorable impact on adoption of cigarette smoking when the media interventions are combined with school programs or other powerful channels of interpersonal influence.

Larger Scale Replication

The design and implementation process used for this program could be replicated on a larger scale at a reasonable level of investment. In this study the mass media intervention was implemented in two widely separated locations, using similar techniques with similar effectiveness. The media tastes of young people in both communities were almost identical. To mount such a campaign on a larger scale would require agreement between media and school program planners on common objectives; access to small student samples for assistance with media intervention development; resources to produce media spots designed to appeal to specific target groups; and money to buy enough

broadcast time in selected markets to ensure high levels of exposure. The average cost of producing a finished television message for this study, including development costs, was $10 369. Average broadcast costs in two small-to-medium markets from 1986 to 1989 were $25 000 per market annually.

Several factors work in favor of achieving consistency between school program objectives and mass media objectives in a larger scale replication. The school program used in this study was explicitly designed in 1984 to represent a good smoking prevention program for the future. Continued strengthening of school health education curricula has occurred since then,[30] with many programs based on objectives similar to those used here. These changes set the stage for more effective collaboration between school-based and mass media interventions.

Conclusion

The interventions for this study were based on three main strategies: (1) common educational objectives for concurrent mass media and school-based interventions, (2) careful targeting of interventions, and (3) maintenance of interventions at high levels of intensity and diversity throughout the critical years for smoking adoption.

Those responsible for directing media interventions should understand the objectives and content of school-based programs being conducted in the broadcast area so that they can reinforce these activities. Media planners also should use diagnostic and formative research to learn about message styles appealing to young people at different developmental stages. Messages should be presented with adequate frequency and variety to promote a lifestyle with positive nonsmoking norms.

The strength of this approach is in the promotion of a lifestyle, rather than a product or a service. There are examples from advertising in which selling a product also promotes a lifestyle, most notably in beer advertising. Taken one at a time, beer commercials sell a product; taken together, they promote an easygoing, highly social lifestyle. The media and school interventions in this study accomplished a similar goal by presenting messages that appeared to come from different sources but had the same educational objectives.

With their appeal to young people, especially those at highest risk for smoking, mass media provide a particularly effective way to deliver smoking prevention messages. The approach developed in this study apparently tapped the power of the media to influence smoking norms among this highly impressionable age group, and prevented significant proportions of them from starting to smoke cigarettes. □

The Second Chicago Televised Smoking Cessation Program: A 24-Month Follow-up

Richard B. Warnecke, PhD, Patricia Langenberg, PhD, Siu Chi Wong, MS, Brian R. Flay, DPhil, and Thomas D. Cook, PhD

ABSTRACT

Objectives. As smoking decreases in the population, the remaining smoking population will change, and cessation initiatives will have to incorporate strategies designed for these smokers.

Methods. To study patterns of response to a cessation intervention composed of 20 televised segments and the American Lung Association *Freedom from Smoking in 20 Days* manual, this study compared cessation rates over 24 months in a cohort of smokers who registered for a cessation program with those in a cohort selected from the smoking population at large.

Results. At post intervention, multiple point prevalence of cessation among participants, adjusted for baseline smoking, was 14% among registrants and 6% in the population; at 24 months the adjusted rates were 6% and 2%, respectively. Heavy smokers benefited more than light smokers, and there was a consistent dose-response relationship between extent of exposure to the intervention and cessation.

Conclusion. The effects of the intervention were strongest for those who read the manual and watched the programs daily. Manual use was important, and those who did not read it did not appear to benefit. Compared to the population and given full participation, heavy smokers benefited more than lighter smokers. (*Am J Public Health.* 1992;82; 835–840)

Introduction

Data obtained in the National Health Interview Survey through 1985 show that about 30% of the adult US population over the age of 20 years smokes.[1] The goal of the US Public Health Service and the National Cancer Institute is to reduce smoking among that population to 20% by the year 2000.[2,3] Other data compiled from the survey indicate that the smoking population of the future is likely to comprise hard-core smokers who either are unmotivated to quit or have failed to succeed at past efforts.[4–6] These remaining smokers have not responded to traditional smoking interventions that have been successfully offered in the past to the general population.[7–9].

Our ongoing research and that of others indicate that these continuing smokers are likely to have needs that limit their capacity to respond to such interventions. Thus, new interventions will probably have to incorporate different strategies to reach these smokers. For example, those who continue to smoke may be most likely to respond to interventions that do not call for attendance at face-to-face meetings and that require minimal reading or provide reading materials that are written at a very low literacy level.[4,10]

Televised smoking cessation interventions that incorporate models to whom these smokers can relate are often used because they reach many smokers. Although some community-based programs have not found televised interventions to be effective without direct, face-to-face support from community health workers,[11,12] others have found otherwise, especially when such interventions are combined with other self-help materials.[9,13] Elsewhere[10] we reported that those at risk to continue smoking were likely to view credible televised programs, such as those offered as part of a news broadcast, and could recall 6 or more of the 20 segments that were broadcast. However, analysis of participation in the intervention also indicated that those who recalled segments of the broadcasts were not the same as those who referred to the accompanying manual. Thus, if the effectiveness of intervention is contingent both on viewing and recalling televised segments and on referring to a manual, the intervention may not fully reach those likely to be the smokers in the future. As we show here, however, the combination of referring to a manual *and* viewing the programs daily predicts the greatest success with the program.

The principal purpose of this paper is to report long-term (24-month) results from the minimal self-help smoking cessation intervention that combined the American Lung Association manual, *Freedom from Smoking in 20 Days,* with a daily series of 20 televised news segments designed to supplement the daily steps described by the manual. These results compare the 24-month multiple point

FIGURE 1—Lagged analysis plan

prevalence of cessation of a cohort of program participants with that of a sample drawn from the smoking population targeted by the intervention. A second purpose is to describe how level of exposure to the intervention affected rate of sustained cessation and timing of the cessation event.

Methods

Design of the Intervention

Details of the intervention and characteristics of the participants are described in detail elsewhere.[10] Briefly, the televised portion of the intervention was broadcast over 20 days as part of the local evening news at 4 PM and 10 PM on WLS-TV, the local ABC-owned station in Chicago. During the 3-week registration period, 10- and 30-second spots, featuring a mime, "kicking the habit," and donated by WLS-TV, were broadcast telling smokers how to register. Through collaboration with the Chicago Lung Association, True Value Hardware stores, and PruCare Health Maintenance Organization, the American Lung Association manual, *Freedom from Smoking in 20 Days,* was distributed at no cost when smokers registered for the program or requested the manual. In all, 9182 smokers registered for the program, and an estimated 75 000 additional manuals were distributed through the stores to those smokers who requested them.

Study Samples

The results reported here are from a sample of 2089 participants and a sample of 2398 smokers in the general population who reported viewing the evening news at least 3 days a week and were not participants. Participants were registrants who, at the first postintervention interview, reported referring to the manual at least once and/or viewing at least one segment of the program.

In October 1986 (6 months before the intervention was broadcast), two population panels were selected through telephone screening from the population of smokers in the Chicago metropolitan statistical area. Their purpose was to provide baseline estimates of population smoking behavior prior to the intervention and to model changes in smoking behavior in that population absent any intervention. Because the two panels were selected to be equal in number, a disproportionate, stratified design was used with directory-based random-digit dialing. We screened 35 541 telephone numbers to obtain 2398 completed interviews.

The population panels were selected from all smokers 18 years of age and older who resided in the six-county area comprising the Chicago metropolitan statistical area, smoked at least seven cigarettes a week, and viewed the late afternoon or evening news at least three times per week (including weekends). The two panels were distinguished by their channel of preference for viewing the evening news as determined by their responses to the initial interview and to a second preintervention interview 3 months later. Smokers who did not watch the evening news were dropped from the panels.

Statistical Methods

To compare the smoking cessation patterns among the participant and population samples over the 24 months following the intervention, adjusting for differences in demographics and baseline smoking, and to model smoking cessation patterns absent any intervention, we used the weighted, combined population data, which is described as the population panel.

A "lagged" analysis compared changes in smoking behavior among subjects in the participant sample and population panel at 50 days and at 6, 12, and 24 months past the "zero" point, defined as the *time of first interview* for the population panel and the *date of the start of the intervention* for the participants. The matching point was arbitrarily selected at 50 days because the median time interval between the intervention zero point and the first postintervention interview was 50 days (see Figure 1). At zero point, all subjects were smoking. At each interview, the exact (or as nearly exact as possible) date of "quit" was ascertained. Because the final interviews were conducted after a 12-month interval, there was no interview at 18 months for the participants or at 24 months for the population. (The population interviews began 6 months before the intervention.) The 24- and 30-month interviews included carefully designed probes for smoking status at 18 months for participants and at 24 months for the population. These data were used to estimate with reasonable confidence the quitting status at the relevant points of comparison for the 6-month point for both samples.

The analysis focused on examining and comparing cessation patterns in the participant sample and the weighted, combined population panel, overall and within intervention exposure groups. Survival analysis (event history) methodology was used to model and plot time to cessation from the zero point. Because respondents were interviewed at different times, they were either quit at the time of interview or censored (final outcome not determined) at the date of the interview. Analyses were made at each interview wave so that each analysis answers the question: "For a respondent who was not smoking at a given interview point, when did the *last* quit without subsequent relapse occur?" The respondent had to have been quit for 3 or more days at the first postintervention interview and for 7 or more days at subsequent postintervention interviews to be considered a nonsmoker. Modeling was performed using the Cox proportional hazards method to adjust for demographic and smoking history variables on which the samples differed in preliminary cross-tabulations. Because the proportional

hazards assumptions were not met for exposure subgroups, this variable was entered as a stratifying variable. Cumulative cessation rate curves (complement of survival curves) were plotted for exposure groups.

Response Rates

In all, 74% of the participants were retained through 24 months, and 51% of the population panel members were retained through 30 months. Rather extensive attrition occurred within the study period, particularly in the population panel. Because the sample was selected using random-digit dialing, in which telephone numbers are selected randomly and include unlisted and directory-assisted numbers, respondents were often lost to follow-up when they changed residence. Although we collected information about a person who would know how to reach the respondent, often this secondary source could not be located or refused to provide the information to locate the respondent.

As shown in Table 1, males, Blacks, low-income, and less-educated respondents were overrepresented among respondents lost to follow-up compared with those who remained over the entire period. Although, as expected in large samples, many of the differences in the table are statistically significant, most of the actual differences are relatively small. Of more importance, the baseline smoking rates did not differ in those followed up compared with the rates in those lost to follow-up. The distribution of smoking behavior at the time of loss to follow-up did not change among those who remained and those who were lost (not shown in the table). Respondents who were not recontacted in a given wave but were recontacted at a later wave were questioned about their smoking status for the missing wave and were retained in the continuous cohort when their smoking behavior for the missing wave could be ascertained.

Results

First, the intervention attracted a disproportionate number of heavy smokers (30 or more cigarettes per day) relative to the population (see Table 1). Female and Black smokers were also overrepresented among participants compared with the population.[10]

We examined point prevalence of cessation following the intervention and multiple point prevalence of cessation at subsequent observation points. Multiple point prevalence is defined here as the cessation rate at any subsequent wave of data collection among those participants and members of the population panel who reported being abstinent for at least 3 days at 50 days post zero point and who reported being abstinent for at least 7 days at each intermediate contact. It is our estimate of continuous cessation; however, as in most studies where it is used, multiple point prevalence is biased because it includes as abstinent any persons who may have slipped between measurement points.

The overall point prevalence of cessation among participants at 50 days post zero, adjusted for baseline smoking level, was 16%; the comparable point prevalence rate in the population panel was 4%. At 6 months, the adjusted multiple point prevalence of cessation was 9% for the participants and 3% for the population; at 12 months, the rates were 6% and 3%, respectively; and at 24 months, they were 6% and 2%, respectively. Relapse during the 6 months following the intervention was greater for the participants than for the population; nevertheless, the 24-month multiple point prevalence rate among the participants was three times that observed in the population.

Table 2 presents these data broken down by average number of cigarettes smoked daily at baseline. Several things are worth noting in the table. First, the point prevalence of cessation at post intervention for each level of baseline smoking is higher among participants than among the population panel, consistent with an intervention effect. Second, light smokers at baseline were more likely than heavy smokers to be abstinent at 50 days post zero. However, although the heaviest smokers among the participants quit at two thirds the rate of the light smokers, the rate of cessation among the heaviest smokers in the population was only 25% of the rate among light smokers. Third, the rate of relapse at 24 months postintervention among light smokers was 70% among the participants and 62% among the population; among the heaviest smokers, it was 60% among the participants and zero among the population. These comparisons suggest that the heaviest smokers in both groups were somewhat better able to sustain their decision to quit than the light

[a]Weighted.

smokers but that the benefits of the program were most obvious in the high initial quit rates among heavy smokers who participated. That is, among light smokers the ratio of initial point prevalence of cessation of participants to that of the population was about 3 to 1 in favor of participants; the comparable ratio among heavy smokers was 7.5 to 1, also in favor of participants.

Figure 2 presents the cumulative cessation rate curves at 50 days post zero and at 6, 12, and 24 months following the intervention, adjusted for gender, race, education, smoking rates at baseline, and self-reported health status. Separate curves were plotted for various levels of participation in the intervention. Participation (n = 1550) was defined at three levels for the plots presented here: *high participation* (10%) accounts for those who watched the televised segments daily and referred to the manual daily; *moderate participation* (37%) accounts for those who watched the televised segments at least once a week and referred to the manual at least two to six times a week; and *low participation* (53%) accounts for those who participated to any lesser extent.

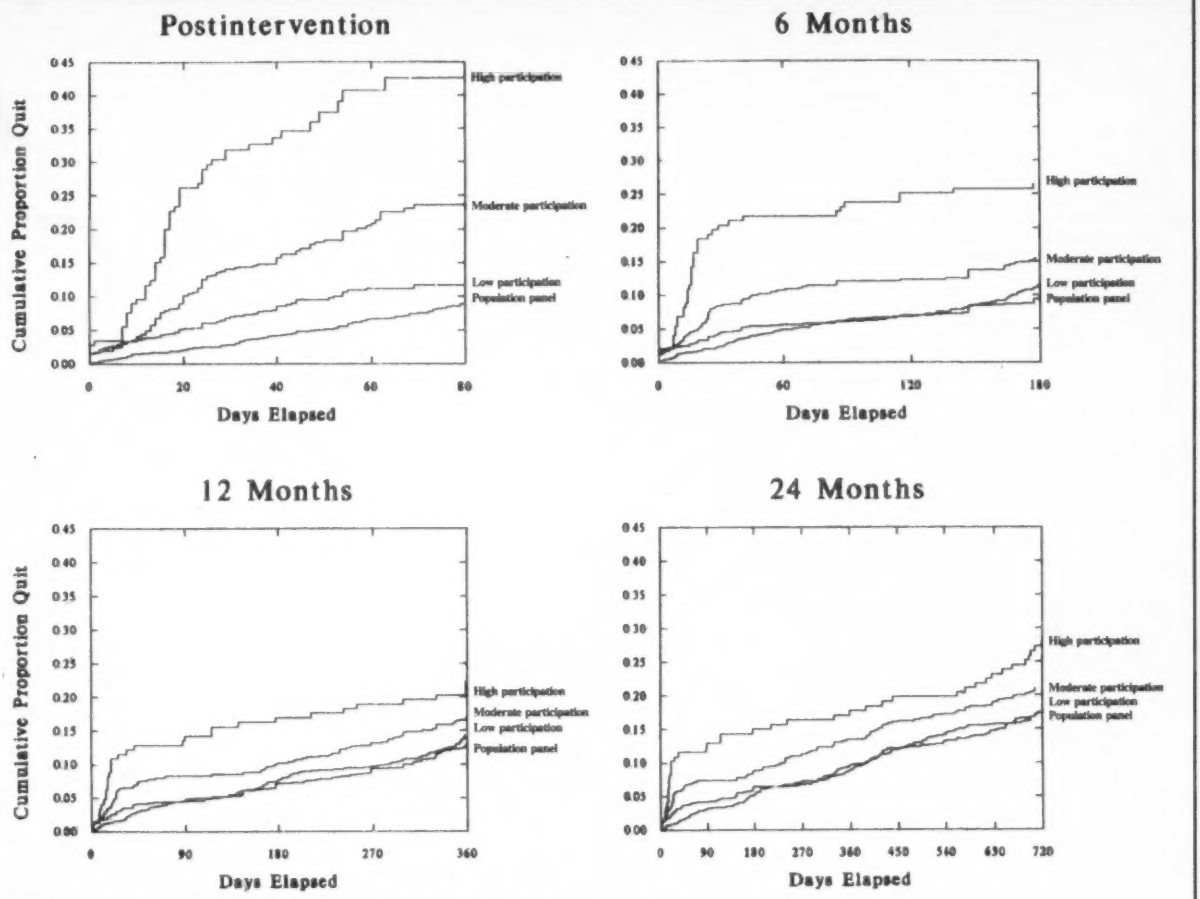
In Figure 2, at each interview wave, even at 24 months, the cumulative proportion quit among high participants was considerably greater than that among moderate participants, low participants, and the population panel. Consistent with the data in Table 2, the greatest contrast is between high participants and the population panel at every point. Also consistent with Table 2, the initial increases in slope for the high and moderate participants indicate that, among those who were abstinent at 24 months, most of the cessation occurred as part of the intervention and clustered around day 18, the quit day specified by the program. The gradual increase in the slope of the low participants is similar both to that of the population and to what would be expected with no intervention.

In Table 3, we present results of the Cox proportional hazards method, predicting cessation across waves of intervention as a function of demographic characteristics, baseline smoking behavior, and overall health status. The variables above the dotted line, which are the variables associated with cessation on which the participants and the population panel differed, are the covariates that were controlled in the Cox proportional hazards analysis. Race and education are sufficiently correlated so that neither appears to have an independent, significant association with quitting. However, having a college education *is* significantly and positively associated with cessation at postintervention compared with having less than a high school education. The association appears to reverse at 12 months. Race is significant only at 24 months, although non-Blacks were more likely than Blacks to be consistently abstinent across all waves. Males were more prone than females to have quit at all points, although the relationship is not statistically significant at 24 months. Health is also an important factor. Those in good health were more likely to be abstinent at each observation; however, the relationship is not significant at the 12-month observation. Only baseline smoking level is consistently associated with cessation through 24 months: lighter smokers were more likely to quit than heavier smokers.

Below the dotted line in Table 3 are the risk ratios associated with participation level. Because the proportional hazards assumptions were not met for the participation variable, the confidence interval estimates should be viewed with caution as they tend to average across time. The inferences support the findings from the cumulative cessation plots that those in the high and moderate participation groups were more likely to quit and remain quit than were those in the population panel, although the effects are not always significant.

Discussion

Participants who followed the program with the greatest regularity were more likely to quit smoking and to sustain their abstinence over 24 months than were those who participated less intensively or individuals in the population who quit without the intervention. Moreover, as seen from the curves in Figure 2, there was a dose-response relationship between level of participation and maintenance of abstinence over 24 months, with larger risk ratios for higher participation categories. Furthermore, the cumulative cessation rate curves show clearly that most of those who were abstinent at 24 months quit initially during the intervention period. Finally, the long-term effects of participation in the intervention were especially evident for heavy smokers, given that those who participated were more likely to quit than were those in the population panel, who did not have access to the intervention (see Table 2). Moreover, among the participants, although light smokers were more likely to quit postintervention, heavy smokers who quit were somewhat more likely to be abstinent at 24 months. Thus,



High Participation = Watched televised segments daily and referred to manual daily
Moderate Participation = Watched televised segments at least once a week and referred to manual at least two to six times a week
Low Participation = Participated to any lesser extent

FIGURE 2—Cumulative cessation rates

all the data are consistent with an intervention effect and suggest particular benefit for heavy smokers.

The target population in this study was defined as those smokers who watched the evening news on the intervention television channel. The demographic characteristics of the viewing audience indicate that the news audience for this channel contained a disproportionate number of those who are likely to be the smokers in the year 2000. These include heavy smokers, low-socioeconomic females, Blacks, and blue-collar workers.[4-6] Therefore, the fact that the participants drawn from this audience did so much better than the quitters from this audience who attempted to quit without the intervention is also quite encouraging, as are the positive effects of the program on heavy smokers who participated. This latter finding is particularly noteworthy, given that heavy smokers were represented disproportionately relative to their distribution in the population.

Based on the risk ratios in Table 3, however, light smokers at each wave of observation were most likely to be abstinent. Although the relationship is not consistently significant, males appear to have had more success with stopping than females, as did smokers in good health. Non-Blacks were more likely than Blacks to quit, and more education favored cessation during the immediate postintervention period. Data from this study reported elsewhere indicate that the heaviest users of the manual were highly educated females.[10] These data also indicate that, although less-educated, Black females were consistent viewers of the televised intervention, they did not read the manual. Males were unlikely to have participated in any aspect of the intervention, but those who did were most likely to use the manual.

Thus, although these data are encouraging about the potential of such interventions, they need to be read with some caution. High and even moderate participation *were* correlated with higher rates of cessation than was low participation; in fact, those who registered and participated only slightly did worse at some waves than did the population panel, as can be seen from the bottom line in Table 3. On the other hand, this intervention may be reaching the same population that has responded to other interventions. This would imply that more attention must be given to developing materials that support the televised component and will make the intervention attractive to and used by those segments of the smoking population who are not being reached by current in-

TABLE 3—Cox Proportional Hazards Risk Ratios for Cessation across Waves of Interviews as a Function of Demographic Characteristics, Baseline Smoking Behavior, and Level of Participation in the Intervention

*$P < .05$.

terventions and who are therefore likely to become the hard-core smoking population of the future.

Attrition was a problem; however, it is unlikely to explain differential outcomes because it was not related to baseline level of smoking or to smoking behavior at the time the subject was lost to follow-up.

Overall, the results of this paper encourage the use of an intervention in which television is combined with written, self-help materials. Taken with other results from this research,[10] they show a need for further investigation of the types of materials that are likely to be effective not only with those smokers who did not respond to the written materials used here but also in most other interventions of this kind. □

Functional Limitations and Disability among Elders in the Framingham Study

ABSTRACT

Background. The measurement of physical disability as an indication of the impact of disease is commonly seen in research. However, these measures often do not clearly differentiate between functional limitations and daily performance of an activity.

Methods. We measured the differences between self-reported disability and observed functional limitations in six activities of daily living tasks among community-dwelling elders. The value of functional limitations vs disability measures in determining risk factors for disablement was ascertained.

Results. Systematic differences were found among the 1453 participants. At least 89% of the time when a difference was identified, the subjects ranked disability greater than the functional limitations observed. For those who were cognitively impaired, discrepancies occurred up to 11% of the time. In determining risk factors for disablement, we found that neurological impairments were associated with both functional limitations and disability, while sociocultural factors were associated with disability only.

Conclusions. Our findings suggest that physical functional limitations and disability in the elderly are two distinct concepts and that the measure of choice should be determined by research objectives and the type of population being studied. (*Am J Public Health.* 1992;82:841–845)

Introduction

Changes in life expectancy have resulted in an elderly population of increasing size and proportion where significant numbers are affected by disability.[1,2] Although physical limitations clearly increase with advancing age, reports of prevalence and severity of disability from existing studies may vary up to 3.1%. Although these differences are small in absolute terms, they can be large in percentage differences across surveys.[3] Methodological differences in obtaining the data and the type of population studied are two sources for these discrepancies.

Efforts to determine the magnitude of disability among elders have been hampered by lack of conceptual clarity.[4,5] Most of the current information on physical disability has been generated from self-report measures of activities of daily living (ADL). Often, these measures do not clearly differentiate between the presence of a functional impairment that makes an activity difficult or impossible to carry out and the actual performance of the activity.[6] Understanding of the methodology used to measure disability and determination of the specific functional limitations will not only improve precision for defining levels of disability among elders but also will increase our understanding of risk factors for disablement.

Important distinctions among concepts measurement in disability research have been addressed in a model developed by Saad Nagi[7,8] in which he proposes that there are three major consequences of disease or pathology. The first is impairment, representing the anatomical or physiological abnormality resulting from a pathologic process; the second, functional limitation, is the loss of ability to perform tasks and obligations of usual roles and normal daily life; and the third, disability, is an individual's behavior pattern that evolves with long-term impairment. In this report, we use Nagi's concept of functional limitation to describe a person's inability or restriction in performing an activity and disability to describe a person's pattern of behavior in daily life.

Documentation of the differences between a person's functional limitations and disability is sparse.[9] To distinguish these differences, we compared self-reported disability in six ADLs with observed functional limitations in the same activities in a controlled setting. Knowledge of the relationship between these two concepts and what factors may cause discrepancies will further understanding of disability measurement.

Methods

The study population was the Framingham cohort, a general population sample of residents of the town of Fram-

ingham, Mass. This cohort of 5209 men and women, aged 28 to 62 at entry in 1948, has routinely been assessed every 2 years for factors related to disease occurrence. The sampling procedures, clinical protocols, and disease determinants have been reported previously.[10,11] During a 2-year period (1983 to 1985), 1453 of the 1826 subjects participating in the 18th biennial cycle completed a disability questionnaire prior to their physical examination. At the time of this exam, 2758 of the original cohort of 5209 had died, 151 were institutionalized, and 474 had refused the biennial examination or were lost to follow-up.

Sixty percent of the participants (870 of the 1453) were women, the mean age was 72 years (range = 63 to 94), and all resided in the community. Because cohort members in nursing homes had on-site examinations and the controlled environment for testing functional limitations was not available, they were excluded from this analysis. The 373 cohort members taking Exam 18 who did not complete the disability questionnaire prior to the examination were also excluded. Those excluded were older (mean age = 76.7) and more likely to be female (64%).

Measures

Reported disability questionnaire. A questionnaire was mailed to Framingham participants 1 week prior to the examination. Each was asked to identify his or her normal day-to-day performance of six basic ADLs as defined by variables from the Katz and Mahoney and Barthel indexes.[12,13] These activities included dressing, grooming, feeding, transferring, walking, and stair climbing. Disability scores were assigned to each response (0 = "uses no help to perform the activity," 1 = "uses a device to perform the activity," 2 = "uses assistance of another person to perform the activity," and 3 = "does not perform the activity").

Functional limitation measure. At the beginning of the exam, a trained nurse measured each participant's ability to accomplish the specific tasks reported on the questionnaire according to a standard protocol. The functional limitation score ranged from 0 to 3 (0 = "did the activity without assistance," 1 = "did the activity using a device," 2 = "required human assistance to do the activity," and 3 = "was unable to do the activity").

Other variables. Several factors thought to influence disability measurement were included in the analyses. Age was dichotomized at below 75 years and 75 years and older. The Folstein Mini Mental State Exam (MMSE), a test of cognition, was administered.[14] MMSE scores range from 0 to 30, with scores of 23 or below reflecting probable cognitive deficits. Perceived health, whether a person lived alone or with others, and documentation of stroke or coronary heart disease, which included myocardial infarction, coronary insufficiency, and angina, were included.

Data Analysis

Cross tabulations between each functional limitation and disability item were performed to determine the frequency and direction of differences across each of the six activities. An extension of McNemar's test was used to determine the significance of differences in the discrepancies between functional limitations and disability,[15] and χ^2 tests were used to determine whether bivariate subgroup differences by age and cognition were statistically significant.

Multiple logistic regressions of discrepancies for each ADL were performed to determine the association with selected variables. The coding for the dependent variable for each ADL task was as follows: 0 = "agreement between functional limitations and self-reported disability in the ADL tasks" and 1 = "self-reported disability greater than functional limitations." The few cases in which the reported disability was less severe than the limitations observed were not included in the analyses. Odds ratios and 95% confidence intervals were calculated for each of the predictor variables. The independent variables were age, living situation, perceived health, cognitive function, stroke, and coronary heart disease.

To demonstrate the potential empirical impact of using functional limitations vs self-reported disability measures, we used two multivariate models to predict the presence of disability using both a sum of the observed functional limitation scores and a sum of the self-reported disability scores. For the first model, the sum of the functional limitations score was dichotomized as follows: 0 = "functionally independent in all ADL tasks by observation" and 1 = "functionally dependent in one or more ADLs by observation." The summary self-reported disability score was similarly dichotomized. The same predictor values were used as in the previous analyses.

Results

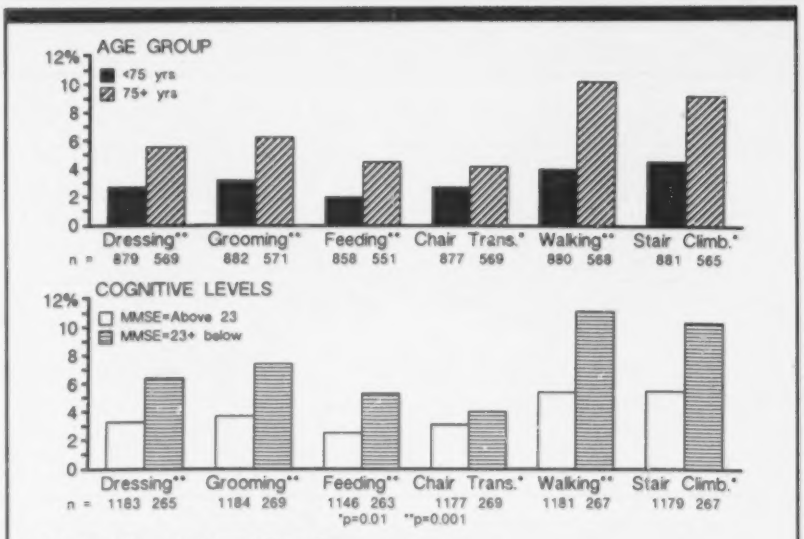
In this study of community-dwelling elders, over 92% of the cohort neither reported disability nor were observed to have functional limitations in the six ADL tasks. Differences did occur between functional limitations and disability in 3.1% to 6.6% of the cohort, most frequently in walking and stair climbing (6.5%) and least frequently in feeding (3.1%). The direction of the differences was highly systematic; at least 89% of the time when a difference was identified, the reported disability was greater than the functional limitations observed (Table 1).

Moreover, when the study sample was examined by age groups and cognitive levels, greater differences were identified. In all six ADL tasks, those who were older and those with cognitive impairment demonstrated significantly larger differences between reported disability and functional limitations (Figure 1). Disparities by age ranged from 3.2% to 4.7% in the below-75 age group and from 4.3% to 10.4% in those 75 years and older. Reported and observed limitations for mobility tasks showed the largest differences by age, with the older group having dif-

ferences of 10.4% in walking and 9.9% in stair climbing. When the sample was divided into those with low cognition scores (MMSE scores of 23 and below) and those within the normal range, the greatest differences between reported disability and observed limitations were seen, with the disparity between functional limitations and disability reaching 11.3% for the cognitively impaired. Again, the largest differences were observed in mobility activities.

The multiple logistic regressions (Table 2) revealed that age, cognitive impairment, and prior stroke were most strongly associated with disparities between functional limitations and reported disability. Stroke was significantly associated with differences in dressing, feeding, and stair climbing. Those in the older age group reported greater disability than the limitations observed in three of the six ADL tasks. Women, the cognitively impaired, those in the older age group, and those who perceived their health as fair or poor reported significantly more disability in walking, the ADL task with the most frequent differences.

To demonstrate the potential value of using a measure of functional limitations vs reported disability in determining risk factors for disablement, we calculated two multivariate models to predict physical disablement. Results of these summary analyses showed that only two of the seven predictors were significantly correlated with both functional limitations and disability scores (Table 3). The two strongest predictors of both functional limitations and disability were stroke and cognitive impairments. The three variables associated with reported disability, but not functional limitations, were age, sex, and perceived health.



Note. MMSE = Mini Mental State Exam.

FIGURE 1—Percentages by age groups and cognitive levels with disagreement between functional limitations and observed disability

Discussion

The results of this study demonstrate that in a cohort of community-dwelling elders, the vast majority neither reported disability nor were observed to have functional limitations. However, those with some restrictions/limitations rarely rated their disability below their functional limitations. These persons reported that their day-to-day disability in specific ADL tasks was greater than the observed functional limitations 89% of the time or more when a difference was identified. These results should dispel the persistent fear that self-report measures of functional disability will yield underestimates of the prevalence of disablement because of the older person's reluctance to admit to his or her limitations.[16] In fact, self-report of disability may yield higher estimates as compared with observed functional limitations if the self-report focuses on the individual's actual behavior in daily life.

Investigators are increasingly using performance testing in large-scale surveys of physical disability in older populations.[9] This trend may reflect legitimate concern that self-reported questions of physical capacities may elicit a subjective response that indicates what older persons think they are capable of, even though they may not normally attempt the activity. Such judgments are subject to potential error and may not accurately estimate the functional ability of the older person. A different challenge is faced when using self-reported disability measures. Here the question is whether or not a particular activity is not performed because of health problems or as a result of other unrelated reasons. Some investigators have used the concept of perceived difficulty in performing ADLs to distinguish the health-related significance of the reported behavior, while others have asked the respondents only to report limitations related to their health.[17-19]

This study examined the hypothesis that performance of ADLs has an integral cognitive component that influences day-to-day function. Those with cognitive impairment showed significantly greater differences between functional limitations and disability. This supports the need for further investigation into the specific manifestations and etiology involved in cognitive impairment and outcome measurements used in this population.[6] The fact that the older age group displayed significantly greater disparity for the ADLs studied, especially for mobility, may be the result of a more cautious life-style.

In general, mobility tasks more than self-care activities were associated with differences between functional limitations and disability. Disparities in walking were significantly associated with age, gender, cognitive impairment, and overall perceived health status of the cohort members.

The last goal of this study was to ascertain whether functional limitations and disability were associated with different risk factors. In other words, does the choice of one or the other influence the findings using the same predictive model? We found that cognitive impairment and history of stroke are the only two risk factors for functional limitations among the six variables in the logistic model. In contrast, disability was associated with four of the six factors, including age, gender, perceived health, and cognitive impairment and stroke. This supports Nagi's formulation that disability, unlike functional limitations, has a major social component.[7] Since disability reflects performance within a sociocultural context, one could expect that daily performance of an activity would be strongly influenced by sociocultural factors. One could speculate that

[e]MMSE = Mini Mental State Exam. 1 = MMSE ≤ 23 (impaired); 0 = MMSE > 23 (normal).
[f]1 = yes; 0 = no.
[g]1 = yes; 0 = no.

TABLE 3—Logistic Regression Models of Predictors of Obeserved Functional Limitations and Disability for All ADL Tasks

	Dependent Variable			
	Functional[a] Limitations		Disability[b]	
	Odds Ratio	95% Confidence Interval	Odds Ratio	95% Confidence Interval
Age (<75/75+)	0.72	0.45–1.17	2.1	1.41–3.10
Sex (male/female)	0.84	0.53–1.33	1.52	1.01–2.28
Living situation (alone/with others)	0.91	0.63–1.33	0.82	0.61–1.12
Perceived health (excellent or good/fair or poor)	1.32	0.97–1.80	2.03	1.57–2.62
Cognition (≤23/>23 on MMSE)	2.55	1.27–5.12	2.58	1.41–4.71
Stroke (absent/present)	3.13	1.47–6.65	2.56	1.27–5.19
Coronary heart disease (absent/present)	0.64	0.31–1.35	1.0	0.49–2.03

Note. MMSE = Mini Mental State Exam.
[a]0 = no functional limitations in all six ADL tasks, 1 = functional limitations in one or more ADL tasks.
[b]0 = no disability in all six ADL tasks, 1 = disability in one or more ADL tasks.

these factors are proxies for other variables that influence disability but not actual functional limitations.

Limitations in the design of this investigation prevent us from determining conclusively the extent to which differences were due entirely to the difference between the functional limitations and reported disability dimensions being assessed. The disability measures differed with respect to the methods used to assess the older person's function: the functional limitations measure relied upon the professional's report of observed behavior, while the reported disability measure relied upon the self-report of the elder. Our analyses are unable to differentiate the degree to which observed differences are due to these different methods. Factors that may influence reported disability include mood, pain, and general feeling of health at the time the questionnaire is completed. Also, the estimates of disability are limited to those who were able to be evaluated at the clinic site, where observation by a professional could influence performance. Therefore, they do not represent those who are more likely to be more disabled at home or in an institution.

Our analyses do not suggest a clear preference for using either functional limitations or disability as the most appropriate outcome variable. Rather, we recommend that the choice between the two measurements be based on the objective of the specific research hypotheses and the population under study. For descriptive questions, this analysis suggests that estimates of prevalence will be similar regardless of whether the focus is on functional limitations or disability. Greater concern, however, should be exercised when the research focus is on high-risk subgroups such as the cognitively impaired, where prevalence estimates can differ to a greater extent. Although differences in prevalence estimates may be small, the choice of measuring functional limitations or disability may seriously affect empirical results. Risk factors for disability and functional limitations may be quite different, as posited by Nagi over 25 years ago. □

Twelfth International Conference on Alcohol, Drugs, and Traffic Safety

The 12th International Conference on Alcohol, Drugs, and Traffic Safety will be held in Cologne, Germany, September 28 to October 2, 1992, and will consider the question of which blood alcohol limits to set for drivers in the united Germany and in the future united Europe. Traffic safety experts from all over the world, legal and medical experts, and psychologists will aim to contribute to a worldwide reduction in the traffic deaths and injuries attributable to drug and alcohol abuse.

The conference will be comparing the effects of legal alcohol limits and police surveillance tactics in different countries. It will also look at alcohol consumption trends in various cultures, the effects of alcohol on driving behavior and accident occurrence, the influence of medication and drugs, and prevention and rehabilitation.

The International Committee for Alcohol, Drugs, and Traffic Safety, formed in Stockholm in 1950, holds a conference every three years on alcohol and driving. The Cologne Conference is being sponsored by the German Federal Ministry of Transport and organized and supported by the TÜV-Akademie Rheinland and the Medical and Psychological Institutes of TÜV Rheinland and TÜV Hannover.

If you register before June 30, 1992, the fee for the five-day conference is DM 750 (including taxes). For further information or to register, contact the conference office at TÜV-Akademie Rheinland, Am Grauen Stein, 5000 Cologne 91, Germany; tel. 0221 806-3062, fax 0221 806-3006.

Neuroleptic Medication and Prescription Practices with Sheltered-Care Residents: A 12-Year Perspective

Steven P. Segal, PhD, David Cohen, PhD, and Stephen R. Marder, MD

ABSTRACT

Objectives. Most adult residents of sheltered-care facilities (board and care, family care, psychosocial rehabilitation, and other supported housing arrangements) for the chronically mentally ill receive neuroleptics. These facilities house over 300 000 mentally ill residents, but neuroleptic prescription practices with this population have not been studied.

Methods. A probability sample (n = 393) of all adult former psychiatric patients in sheltered care in California was surveyed in 1973; 94% of the located survivors (n = 243) were reinterviewed 12 years later.

Results. In 1973, 79% received neuroleptics; in 1985, 76%. Polypharmacy decreased, and the elderly remained less medicated than adults. Yet, mean daily neuroleptic doses doubled, more persons received higher doses, and 62% reported adverse effects. Furthermore, high dosing was attributed to psychiatrists rather than other physicians, even when controlling for residents' clinical and sociodemographic characteristics.

Conclusions. Neuroleptic drugs became the staple pharmacological treatment for mentally ill sheltered-care residents. While physicians more cautiously medicated the elderly, they had not reduced doses by 1985, even after a decade of treatment. The specialty of the prescriber was an important factor in preference for high-dose treatment. (*Am J Public Health.* 1992;82:846–852)

Introduction

More than three quarters of the adult residents of sheltered-care facilities with a history of mental hospitalization are prescribed neuroleptic drugs.[1] Because long-term use of neuroleptics, which delays relapses in over 50% of schizophrenic patients,[2] also poses great risk of persistent tardive dyskinesia,[3] researchers and professional associations have recently urged clinicians to exercise caution when prescribing these drugs.[4,5] This study describes psychiatric drug prescriptions in a cohort of residents in sheltered care (board and care, family care, halfway houses, and psychosocial rehabilitation facilities). Specifically, we consider prescription practices in the mid-1980s to determine how they changed from the early 1970s.

A partial consensus concerning the use of neuroleptics emerged in the 1980s around four issues. First, although medications such as antiparkinsonians or antidepressants are commonly added to neuroleptic regimens, the simultaneous prescription of more than one neuroleptic or more than three psychotropics has been particularly criticized.[6,7] Second, there has been considerable interest in low-dose strategies,[8–11] which are sometimes associated with higher relapse rates but usually with improved social functioning and fewer adverse effects.[12–15] Third, although high- and low-potency neuroleptics are considered equally effective,[16,17] maintenance treatment with injected depot preparations has been recommended[10,14,18] to circumvent most patient noncompliance and ensure exact dosage delivery. Fourth, since the likelihood of noncompliance, adverse effects, and errors in administration increases with the frequency of administration, once-a-day dosing has been recommended for oral maintenance treatment.[19–21]

Most experts writing in the mid-1980s recommended general adherence to these four prescription practices, but the subject has not been studied extensively in recent years and the literature abounds with contradictory anecdotal impressions.[22,23] No study has examined prescription practices in a cohort of former patients living in community-based sheltered-care settings. This is an important omission, for these facilities have become the placement of choice in the mental health system, housing 300 000 to 400 000 mentally ill adults.[24]

Methods

This 12-year longitudinal study first involved face-to-face, structured interviews in 1973 with 393 residents of 211 sheltered-care facilities in 157 census tracts in California, a self-weighting probability sample of all 18- to 65-year-old formerly hospitalized ex-patients (n = 12 430) in sheltered care in the state.

The sample was obtained by dividing the state into three master strata: Los Angeles County, the nine-county San Francisco Bay Area, and all other counties. In the first two, facilities were stratified by

This paper was submitted to the Journal June 10, 1991, and accepted with revisions November 27, 1991.

size and a sample was drawn of facilities with probabilities proportionate to bed capacity. In the third stratum, a cluster sample was designed, selecting two counties from the northern and two from the southern part of the state with probability proportionate to size. From each pair, samples of facilities were selected, also with probability proportionate to size. Residents were sampled within facilities, using systematic random sampling from specially prepared field listings.[25]

Follow-up data were collected in 1985. Of the 393 former residents, 360 (91.6%) were located and 33 (8.4%) were not. Of the former residents located, 270 (68.7%) were alive and 90 (22.9%) confirmed dead. Of the survivors, 253 (93.7%) were interviewed, and 243 (90%) yielded complete drug information. This study focuses on psychotropic drug prescriptions to these 243 survivors (61% of the original sample). Table 1 shows no differences between the two samples except for the survivor sample being younger and having more women and fewer Blacks than the original, due to higher death rates among the elderly, men, and Blacks.

In 1973 and 1985, drug prescription data (name of drug, dosage, times per day, number and frequency of injections) were obtained from respondents and their residence managers or physicians. All active prescriptions at the time of the interview were recorded. Self-reported dosages were confirmed by checking prescription bottles. Neuroleptic dosages from both years were converted into oral chlorpromazine equivalents (CPZeq) using Hollister's[26] scale. For the injectable, long-acting fluphenazine decanoate, CPZeq was determined by a first equivalence to daily units of fluphenazine hydrochloride, using the rule endorsed by the manufacturer of Prolixin® and by other psychopharmacologists[27,28]: 12.5 mg of fluphenazine decanoate injected every 3 weeks is equivalent to 10 mg of fluphenazine hydrochloride daily. Unless otherwise noted, all dosages are reported in mg/day CPZeq.

Information on adverse drug effects was obtained only during the 1985 study, with respondents asked to rate the severity of 13 effects from "absent" to "very severe."

Chi-square tests, two-tailed *t* tests, and multiple regression analysis were performed on the data using the SPSSx statistical package. Significant results are reported when $P < .05$.

TABLE 1—Characteristics of Chronic Mentally Ill Patients (n = 393) Living in Sheltered-Care Facilities in California in 1973, and Cohort Survivors with Psychotropic Drug Data (n = 243)

Results

Cohort Status

In 1973, 213 persons (87.6%) received a psychotropic drug prescription, compared with 206 (85.2%) 12 years later.

In 1973, 79% of the residents were prescribed neuroleptics, 81% of women and 77% of men. By 1985, 76% received these drugs, and women were significantly more likely to be prescribed neuroleptics (82% vs 71%, $\chi^2 = 3.8$, $df = 1$, $P < .05$), the only significant gender difference detected in the prescription of any psychotropic. Table 2 shows how many patients were prescribed how many drugs per class.

Diagnosis and medication. Lifetime modal diagnoses based on hospital discharge data were determined for 209 of the 243 sample members. Most (79%) received diagnoses of schizophrenic disorders, the rest substance abuse (5%) or other disorders (16%). Modal diagnoses for 162 (88%) of those on neuroleptics in 1985 were: schizophrenia or other psychoses (87%), affective disorder (6%), and other disorders (7%).

Diagnoses were available for 26 (93%) of 28 persons prescribed an antidepressant in 1985. Only 5 (20%) had any diagnosis of affective disorder noted in their lifetime hospital records. Of 9 persons prescribed lithium at follow-up, only 2 had any such diagnosis. There were no sex or age differences in the likelihood of receiving these drugs without the diagnosis.

Neuroleptic drugs. Ten different neuroleptics were prescribed in 1973, eight at follow-up. Of 192 persons on neuroleptics in 1973, 164 (85%) still received them 12 years later. In the interval, only thio-

Others[d]	4	...	...	2.8	...	...

Note. MDD = mean daily dose.
[a]Total exceeds 100% as patients may have received more than one drug.
[b]$t = 1.97$, $df = 30$, $P < .05$.
[c]In mg/day chlorpromazine equivalent.
[d]In 1973, these are piperacetazine, prochlorperazine, reserpine, and acetophenazine. In 1985, they are chlorprothixene and perphenazine.

ridazine's mean daily dose (MDD) showed a significant reduction (see Table 3).

Prescription Practices

Polypharmacy. In 1973, the mean (±SD) number of drugs prescribed per person was 1.9 (±1.2), reduced to 1.7 (±1.2) in 1985 ($t = 2.13$, $df = 242$, $P = .03$). However, the proportion receiving three psychotropics dropped from 21.4% to 13.2%. Over the study interval, 34% received the same number, 38% received fewer drugs, and 28% received more drugs. Table 4 highlights a reduction of multiple neuroleptic prescriptions, from 29% of the whole sample prescribed two or more neuroleptics in 1973 to 13% by 1985.

Among the medicated elderly, 51% were prescribed one drug, 27% two drugs, and 23% three or more. The comparable percentages for the younger group are 31%, 44%, and 25%, respectively ($\chi^2 = 8.83$, $df = 2$, $P = .012$).

Neuroleptic drug dosage. Among those prescribed neuroleptics in both 1973 and 1985, the MDD (±SD) increased from 512 (±435) mg in 1973 to 963 (±1603) mg in 1985 ($t = 3.64$, $df = 163$, $P = .0001$). Six percent were prescribed the same dose both years, and the rest were evenly split between decreases (46%) and increases (48%). After excluding fluphenazine decanoate, a significant MDD increase was still observed, from 461 (±371) mg to 790 (±1480) mg ($t = -2.72$, $df = 143$, $P = .007$).

The range of neuroleptic dosages increased from 30 to 3400 mg in 1973 to 20 to 11 300 mg in 1985. While only 4 persons (1.6%) in 1973 were prescribed doses over 2000 mg daily, this had increased to 20 persons (9%) by 1985, of which only 3 resided in institutions (where dosages are typically higher). The proportion receiving over 1000 mg daily doubled over the study interval, from 11% to 23%.

Long- and short-acting injectables. In 1973, 6 people (2.5%) received neuroleptics by injection, all of them of fluphenazine decanoate. At follow-up, 22 people (9%) received injections, 16 (7%) of the decanoate products and the others of short-acting neuroleptics.

The MDD of those receiving injections in 1985 was four times greater than that of those receiving oral prescriptions: 2691 (±2585) mg vs 662 (±1130) mg ($t = 3.73$, $df = 21$, $P = .0001$). The mean age in the first group was 46 (±11) years, compared with 55 (±12) years for others ($t = 3.26$, $df = 182$, $P = .001$). They were also prescribed an average of 3 (±1.3) psychotropic drugs, compared with 1.9 (±0.9) for those on oral neuroleptics ($t = -3.70$, $df = 24.16$, $P = .001$).

Age, gender, and dosage. In 1973, the MDD (±SD) among the neuroleptized elderly was 308 (±424) mg (range: 50 to 2060 mg). By follow-up, this had increased to 484 (±753) mg (range: 25 to 4500 mg) but was still less than half that prescribed to persons under 60 (1154 [±1793] mg). This elderly-to-adult dose ratio follows

well-established guidelines to prescribe one third to one half the usual adult dose.[29] However, whereas 36% of elderly on neuroleptics in 1973 were receiving low (under 150 mg) daily doses and 27% were receiving high doses (over 300 mg), by 1985 these proportions were reversed. Over the study interval, increases in MDDs were significant among both men and women, but changes in dosage were not related to gender.

High- and low-potency neuroleptic. Of those prescribed neuroleptics both years, 40% remained on the same potency at follow-up, 18% switched from low to high, and only 5% went from high to low. Most who started neuroleptic treatment after 1973 were prescribed high-potency drugs at follow-up.

During both study periods, high-potency agents were prescribed at significantly higher CPZeq doses than low-potency drugs, and this relative difference had greatly increased by 1985. The high-potency to low-potency dose ratio went from 1.74:1 in 1973 to 5.3:1 in 1985 (excluding fluphenazine decanoate at follow-up, the ratio was 4.6:1).

At follow-up, people receiving neuroleptics of both potencies (n = 25) were (1) more likely to be prescribed antiparkinsonians (56% of them and 52% of the high-potency group, compared with 32% of the low-potency group; $\chi^2 = 7.16$, $df = 2, P = .03$); (2) prescribed more psychotropic drugs on average (3.2 [±0.9], compared with 1.9 [±1.1] for those on high-potency drugs and 1.6 [±0.8] for those on low-potency drugs [F = 21.4, $P = .0001$]); and (3) prescribed drugs more frequently (2.9 [±1.1] times per day, compared with 2.4 [±0.9] for those on high-potency drugs and 2.1 [±1] for those on low-potency drugs [F = 3.9, $P = .02$]). No significant age or sex differences between the three groups were noted.

Daily dosing schedule. The mean maximum daily dosing schedule decreased nonsignificantly from 2.2 (±1.3) times in 1973 to 2.0 (±1.3) times in 1985.

Practice Differences between Psychiatrists and Other Physicians

At follow-up, the medical specialty of the current prescribers of 115 (73%) of the patients on neuroleptics in 1973 and 1985 was known. For people (n = 84) with prescriptions from psychiatrists, the MDD (±SD) increased from 483 (±440) to 1087 (±1648) mg ($t = -3.46$, $df = 83$, $P = .001$), while for those (n = 31) with prescriptions from nonpsychiatric physicians, the MDD (±SD) decreased from 1973 to 1985 from 431.5 (±377) to 263 (±295.5) mg ($t = 2.06$, $df = 30$, $P = .048$). No difference existed between dose levels of these two groups in 1973. This same pattern was observed for the 48 people over age 59 in 1985. For the 20 elderly with prescriptions from other physicians in 1985, the MDD (±SD) decreased from 495 (±447) to 202 (±196) mg ($t = 2.88$, $df = 19$, $P = .009$). For the 28 with prescriptions from psychiatrists, the MDD (±SD) increased from 339 (±231) to 667.5 (±780) ($t = -2.24$, $df = 27$, $P = .033$).

More problematic patients may be referred primarily to psychiatrists, so we sought to determine whether their patients differed from those seen by other physicians. We found no significant differences between them in total time spent in the hospital, number of hospitalizations between 1973 and 1985, Brief Psychiatric Rating Scale (BPRS) scores in 1985, or type of residence in 1985. However, those with prescriptions from psychiatrists were younger (mean age of 52.55 years vs 58.31 years; $t = 2.86$, $df = 155$, $P = .005$).

To predict CPZeq dose at follow-up, we entered the following variables in a multiple regression: age, 1973 BPRS score, 1985 BPRS score, 1973 CPZeq dose, number of hospitalizations, location in an institutional setting in 1985, and whether the neuroleptic was prescribed by a psychiatrist or other physician in 1985. Our model explained 22% of the variance in 1985 CPZeq dose (F = 5.87, $df = 7.148$, $P = .0000$). Significant predictors were the number of hospitalizations ($t = 2.06$, $P = .04$), age ($t = -1.99$, $P = .05$), and who prescribed the neuroleptic ($t = 2.46$, $P = .01$). Psychiatrists were more likely to prescribe at higher doses, even after taking all other factors into account.

We also examined people (n = 41) who were receiving over 1000 mg/day CPZeq, considered excessive by American Medical Association standards.[30] Of these 41, the specialty of the prescriber was available for 27 people. Of these 27, 26 (96%) were prescribed their neuroleptic by a psychiatrist. Mean age among those 26 was 47.5 years and mean time since their last hospitalization was 7.2 years.

Most neuroleptic dose-level differences observed here result from a psychiatric preference for high-potency drugs. Of those people with neuroleptic prescriptions from psychiatrists, 72% received high-potency drugs, compared with 46% of those who saw another type of physician ($\chi^2 = 6.82$, $df = 2$, $P = .0329$).

Adverse Effects

Of the 185 people on neuroleptics in 1985, 62.5% reported at least a mild degree of 1 or more of 13 adverse effects; 26.7% reported experiencing 1 to 2 effects, and 35.8% reported 3 to 13 effects (see Table 5).

Age, gender, and adverse effects. For each adverse effect except weight gain/loss, a greater proportion of people under 40 years reported discomfort. Dry mouth/throat, inability to sit still, depression/apathy, skin rashes, and loss of sex drive were reported significantly more by

TABLE 5—Prevalence of Self-reported Medication Side Effects, 1985

Side Effect	Degree of Severity: Mild n	Mild %	Moderate n	Moderate %	Severe or Very Severe n	Severe or Very Severe %	Total %
Dry mouth or throat (n = 175)	27	14.6	21	11.4	19	10.2	36.2
Restlessness/can't sit still (n = 176)	19	10.3	21	11.4	10	5.4	27.1

Dizziness/weakness (n = 175)	18	9.7	8	4.3	9	4.8	18.8
Skin rash/sensitive to sun (n = 175)	12	6.5	15	8.1	5	2.7	17.3
Problems staying awake (n = 178)	15	8.1	8	4.3	4	2.1	14.5
Sight/eye problem (n = 173)	8	4.3	9	4.9	9	4.9	14.1
Loss of sex drive (n = 171)	4	2.2	10	5.4	10	5.4	13.0
Body rigidity/stiffness (n = 175)	9	4.9	4	2.2	8	4.3	11.4
Spasms of head/neck/mouth/jaw (n = 176)	4	2.2	7	3.8	3	1.6	7.6
Nausea/vomiting (n = 175)	9	4.9	3	1.6	2	1.1	7.6

younger patients. Women and men did not differ in the number of side effects they reported, but women were significantly more likely to report dizziness/weakness, changes in weight, and sight or eye problems.

Adverse effects and prescription practices. Scores of the severity ratings of all 13 adverse effects were summed to produce a total score (possible range: 0 to 52) ranging from 0 to 30 (mean [±SD] = 4.56 [±0.1]). Most people (38%) scored 0; 27% scored from 1 to 4, 20% from 5 to 12, and 15% from 13 to 30. Exactly half the sample reported two mild or one moderately severe side effect. Both the number ($r = .17$, $P < .01$) and the severity ($r = .17$, $P < .01$) of adverse effects showed modest positive correlations with neuroleptic dosage but no significant relationship with neuroleptic potency.

Discussion

Between 1973 and 1985, some psychotropic prescription practices with sheltered-care residents were modified while others remained unchanged. On the positive side, nearly 40% of the sample received fewer drugs at follow-up. Multiple neuroleptic prescriptions were reduced by more than half. The proportion of people prescribed neuroleptics and antiparkinsonians stayed the same over the 12-year period, confirming that these drugs constitute the staple pharmacological treatment for long-term patients. Similarly, the elderly continued to receive, on average, half the neuroleptic dosage prescribed adults. However, overall changes in neuroleptic dosage patterns contrast with published statements such as "unquestionably, concern about tardive dyskinesia has led to more conservative use of antipsychotic drugs; i.e., more careful selection of patients for long-term therapy and the use of lower doses."[22]

We found that 85% of those prescribed neuroleptics in 1973 received them 12 years later and observed substantially higher mean daily doses across age, sex, and ethnic categories. Nearly half of those prescribed neuroleptics both years experienced a dose increase in the interval. Nearly 10% received over 2000 mg CPZeq daily, an extreme dose usually accompanied by polypharmacy and more frequent drug administration. Reflecting their current acceptance as specific treatments for affective disorders, antidepressants and lithium were increasingly prescribed, but most commonly as adjuncts to neuroleptics.[21]

The large increase in MDD is associated with growing use of high-potency neuroleptics. This longitudinal study of long-term sheltered-care patients confirms reports from cross-sectional studies that higher CPZeq doses are prescribed when using high- vs low-potency neuroleptics.[31,32] In this sample, the high- to low-potency ratio is two times that reported in previous studies. This should be of concern, since some evidence suggests that, compared with moderate doses of neuroleptics, higher doses of high-potency drugs frequently produce neurotoxicity and inferior antipsychotic effect.[30,33]

These patterns of dissimilar dosing might be explained by the fact that low-potency agents carry an increased risk of inducing autonomic dysfunction and systemic toxic reactions that are less common or severe when lower doses are used.[34] Some authors[33] find good evidence that high CPZeq doses are not more beneficial than moderate doses but believe that "the recently popular aggressive use of high-potency neuroleptic agents in high doses is to increase the degree and speed of therapeutic response." Our findings indeed suggest that prescribers (primarily psychiatrists) are opting for drugs permitting large dose increases. The higher incidence of extrapyramidal effects associated with these drugs may be considered more acceptable than the autonomic and other physical effects associated with high doses of low-potency drugs.

Patients who had medication switched from low potency to high potency may have been poor responders initially who showed improvement with a drug change and a dose increase. On the other hand, studies indicate that only a small proportion of poor responders at conventional dosages will respond at substantially higher doses.[35,36] That nearly 40% were prescribed the same neuroleptic 12 years apart may denote a stable clinical profile and the patient's acceptance of drug treatment. However, if clinicians should aim to decrease total exposure to neuroleptics, that 60% were switched is disturbing, since nearly two thirds who were switched received a higher CPZeq dose. A possible development of tolerance to neuroleptics could explain increased doses over time in the same individuals, especially if treating physicians remained the same, but we possessed no data on this variable. Possibly, increase in MDD with high-potency neuroleptic was a response to observations in

the late 1970s supporting high doses and rapid neuroleptization in hospital settings,[37] a practice currently in relative disfavor. Patients may have been discharged on higher doses that, in turn, increased during the next hospitalization or convinced clinicians that higher doses were relatively safe. We expect that these attitudes changed during the late 1980s, when concerns about toxic effects of potent neuroleptics were raised[38]: the continuation of our follow-up study to include 20-year evaluations in 1993 will either support or disprove this interpretation.

Nevertheless, in both 1973 and 1985, 4 in 10 patients received neuroleptic doses under 300 mg CPZeq per day, confirming that many chronic schizophrenic patients in the community can be maintained in lower dose ranges.[13,39,40] On the other hand, low-dose strategies must be complemented by community services that can respond effectively to signs of impending relapses. Unfortunately, the level of services available for this population may make low doses appear impractical to prescribers.

One subset of prescribers, nonpsychiatric physicians, appears to follow more cautious guidelines than their psychiatric colleagues, perhaps because of the former's lesser familiarity with neuroleptics and managing adverse effects. We could not locate similar observations in the literature; these practice differences require further investigation.

Nearly 40% of our respondents reported moderate to very severe adverse effects. Restlessness, body rigidity, or orofacial spasms—effects indicative of extrapyramidal symptoms—were reported by 33% of the sample. Several studies suggest that self-reports of extrapyramidal symptoms yield false negative results,[41,42] but our rates are consistently similar to those reported in a multicenter study[42] of 2391 patients on neuroleptics that used self-reports and observer reports.

Dose-related adverse effects typically caused by low-potency agents—such as dry mouth—may be easily recognized and managed by a dose reduction or a switch to high-potency agents. In turn, extrapyramidal symptoms typically induced by high-potency agents—such as akathisia—imitate schizophrenic symptoms[40] and may be managed by reducing the dose but also by prescribing antiparkinsonians. That subjects on high- and combined-potency treatment received significantly higher CPZeq dosages and more psychotropic drugs would seem to support observations from at least one study[43]: when diagnosing neuroleptic-induced extrapyramidal symptoms, clinicians inevitably added an antiparkinsonian rather than reduce the neuroleptic dose.

Clinicians who prescribe neuroleptics to long-term patients may thus err on the side of overtreatment. However, the elderly as a group receive about half the neuroleptic dosage younger patients receive, which suggests clearly that clinicians recognize the need to mitigate neuroleptics' negative effects on the most fragile patients. On the other hand, clinicians appear to respond to the opposing pressure to "do everything possible" to forestall relapses.[13] Since psychotropic drugs often constitute the only tool of the prescriber, this opposing pressure might translate to a reluctance to prescribe less. □

Eligibility for Publicly Financed Home Care

ABSTRACT

Objectives. Proposals for publicly financed home care for the elderly now tend to include cognitive impairment criteria as well as activities of daily living (ADL) criteria. The numbers of elderly deemed eligible for services will depend on the definitions of ADL and cognitive impairment used.

Methods. Data from the 1984 National Long-Term Care Survey were used to generate a series of estimates of the community-dwelling elderly with ADL disabilities and cognitive impairment.

Results. When only ADL criteria are used, estimates of disability range from 472 000 to over 3 million (1.6% to 12.5% of the community-dwelling elderly). These estimates increase to approximately 1 million to 4.2 million (3.5% to 14.0% of the community-dwelling elderly) when cognitive impairment criteria are added.

Conclusions. The use of more stringent or more liberal eligibility criteria will have dramatic effects on the number of elders who qualify for services. The nature of the eligibility criteria employed in any expansion of federally financed home care benefits will be a major factor in determining the costs of such a program. (*Am J Public Health.* 1992;82:853–856)

Introduction

At present, there is no uniform federal policy for financing home care services for elderly persons in need of long-term care. Eligibility criteria that determine who is eligible to receive publicly financed home care services varies considerably by funding source. To a large extent, these criteria are established at the state level, because states have primary responsibility for allocation decisions under many of these funding mechanisms, particularly Medicaid. However, recent congressional proposals to expand federal coverage of home care have stipulated with increasing specificity uniform criteria for eligibility based on functional disability. Typically, these criteria rely on measures of disabilities in a given number of activities of daily living (ADLs).

Eligibility rules that rely exclusively on functional disability criteria have been criticized for excluding persons who have the physical capacity to perform ADLs, but not the ability to remember when to initiate a task, and those who need supervision or cuing in order to complete a task. These are typically individuals who have Alzheimer's disease or a related disorder and who are cognitively impaired. Most legislative proposals for expanding federal financing for home care now include criteria intended to capture the cognitively impaired population targeted for services.

Although nearly all proposals have been specific about the number of ADL disabilities necessary to qualify a person as eligible for services, only a few go so far as to define how disability in a specific ADL would be measured. If implemented, any of these proposals would have to develop more precise criteria for defining an ADL disability in order to ensure equitable access to program applicants. As Stone and Murtaugh have demonstrated, estimates for the number of persons with disability can range widely depending upon the ADL definition invoked.[1]

As nonspecific as some of the ADL eligibility criteria in the expansion proposals are, they are vastly more specific than language pertaining to criteria that would establish eligibility based on cognitive impairment. This lack of specificity regarding cognitive criteria is not simply a deficiency in policy development, but reflects the state of the art in measuring and screening for cognitive impairment in the elderly population.

To demonstrate how cognitive impairment may be operationalized within the context of eligibility criteria, we present estimates of the number of functionally disabled *and* cognitively impaired community-dwelling elders. We vary both the definition of functional (ADL) disability and the definition of cognitive impairment, and show how sensitive estimates can be to the criteria on which they are based.

Methods

Data

Data from the 1984 National Long-Term Care Survey (NLTCS) were used to generate estimates of functional disability and cognitive impairment. As part of the NLTCS, in-depth interviews were conducted of a sample of Medicare beneficiaries aged 65 years and older on April 1, 1984, who were found to have either an ADL or an Instrumental Activity of Daily Living (IADL) limitation.[2]

Estimates are based on the community-resident (noninstitutionalized) sample of the NLTCS. They have been subjected to a weighting procedure whereby cross-sectional weights were applied to adjust for nonresponse and the complexities of the sampling design. Application of weights results in nationally representative estimates of the community-dwelling population aged 65 years and older. All estimates presented in this paper meet precision standards of relative standard errors of 30% or less, and are based on unweighted cell sizes of 400 or larger. Because the estimates derived from the survey reflect the number of persons disabled in 1984, we have adjusted 1984 estimates to be consistent with 1990 population estimates for the population aged 65 years and older.

ADL Disability Measures

Estimates of functional disability are based on the same alternative definitions of ADL disability as used by Stone and Murtaugh, and the methods used to derive them are replications of the methods of Stone and Murtaugh.[1] The estimates were developed from specific questions posed to NLTCS respondents or their proxies regarding the types of help the respondent received in five core ADLs: bathing, dressing, toileting, transferring, and eating. Receipt of services is used in these analyses as an indicator of disability.

The NLTCS asked multiple questions about functioning in each of the five ADLs. Disability in ADL was defined in three different ways, according to the type of assistance required to perform a given ADL.

- Receives active assistance to perform an ADL
- Receives active or standby assistance to perform an ADL
- Receives active or standby assistance to perform an ADL or uses an assistive device in performing an ADL

All estimates refer to ADL disabilities that were chronic in nature, that is, those that had lasted for 3 months or longer.[1]

Cognitive Impairment

The NLTCS was not specifically designed to estimate the number of elders with cognitive problems; thus we were able to derive cognitive impairment estimates only for persons who met the functional disability screen for the NLTCS sampling frame. However, the NLTCS sampling frame for identifying disabled community elders was quite liberal in its definition of disability. Any type of assistance, human or mechanical, for any ADL (i.e., core ADLs plus bladder or bowel incontinence, indoor mobility, outdoor mobility) or for any IADL (meal preparation, laundry, light housework, grocery shopping, money management, medication management, telephoning) that had lasted, or was expected to last, for a minimum of 90 days was included in the definition. Given the wide net that the NLTCS cast in its sampling frame of the elderly disabled, as well as the fact that most cognitively impaired elders can expect to have at least some limitation in functioning, we are fairly confident that elders with cognitive impairments are sufficiently represented in the estimates that follow.

Three definitions of cognitive impairment were developed. The first includes persons with an error score of 4 or more on a modified Short Portable Mental Status Questionnaire (SPMSQ). The SPMSQ is a 10-item screening instrument designed to identify elderly persons with probable cognitive impairment.[3] A score of 4 or higher, rather than the customary 5 or higher, was used to indicate cognitive impairment because one of the SPMSQ questions was altered in the NLTCS, resulting in fewer errors than the original item typically elicits. The cutoff point indicating cognitive impairment was adjusted downward to accommodate this modification. This measure of cognitive impairment is referred to as "CI" in Table 1.

SPMSQ data are missing for those sample members who were not capable of responding to the questionnaire and whose information was provided by a proxy. To identify sample members with missing SPMSQ information who were cognitively impaired, alternative criteria were developed. If a person with missing SPMSQ information was judged to be senile by the respondent's proxy, or if the proxy reported that the person had a disability caused by disorders classified as mental retardation or senile psychotic conditions, the person was considered to be cognitively impaired.[4]

The second definition of cognitive impairment, an attempt to operationalize eligibility language from some legislative proposals, includes evidence of behavior problems along with the CI criteria described above. Some argue that behavior problems should be considered in determining the need for long-term care services because such problems require supervision and oversight to ensure the health and safety of the afflicted person.

Wandering, frequent temper tantrums, and compulsive stealing are the behaviors on which the NLTCS collected information, and are therefore the behaviors represented in our behavior problems (BP) measure. Because the NLTCS did not collect information on other types of behavior problems, our results may underestimate the prevalence of behavior problems among the elderly.

The third definition of cognitive impairment employed in our estimates is more stringent than the other two. Under the "CI+" measure, a person must not only meet the CI criteria but must also either demonstrate disability (i.e., must receive active or standby assistance for 3 months or longer) in at least one ADL or one of the cognitively oriented IADLs (money management, medication management, telephoning) *or* exhibit a behavior problem. For a person to be considered cognitively impaired under this definition, there must be evidence of the need for oversight or some type of assistance. The CI+ criteria is an attempt to operationalize language in proposed legislation that stipulates that a person with Alzheimer's disease or other cognitive impairments must demonstrate needs similar to those of persons meeting ADL criteria in order to be deemed eligible. The CI+ criteria operationalize such criteria by requiring some evidence of the need for care beyond a diagnosis or a score on a cognitive-impairment screen. A diagnosis or a score may not reflect the fact that an impairment is severe enough to require home care services.

Estimates

Table 1 presents estimates of the number of disabled community-dwelling elderly based on alternative ADL as well as alternative cognitive impairment criteria. In each section, the first column represents the number of persons estimated to be disabled based on functional criteria alone. The remaining columns reference

estimates of the number of ADL-disabled *or* cognitively impaired persons; the differences in estimates between the last three columns are a function of the definition of cognitive impairment invoked.

For example, the estimate in the first column of section A for 2+ ADLs represents the number of elders estimated to have two or more ADL disabilities, where disability is defined as the need for the active assistance of another person to perform the ADLs in question.

The estimate in the second column references the number of elders who would be eligible for services if the criterion were 2+ ADLs *or* CI *or* BP. This decision rule targets individuals with two or more ADL disabilities (active assistance only) *or* those who are cognitively impaired (those who score 4+ on the SPMSQ or who have a cognitive impairment–related diagnosis) *or* those who exhibit one or more behavior problems (wandering, frequent temper tantrums, or compulsive stealing). The rationale for considering those with behavior problems within the cognitive impairment group is that behavior problems are considered an indicator of cognitive impairment, and those with behavior problems are thought to need oversight and supervision to ensure their health and safety.

Slightly more than 2 million elders would meet the 2+ ADLs (active only) *or* CI *or* BP criterion in 1990. Approximately 1 million additional persons (or 3.5% more of the elderly population) would be eligible for services if this criterion were used instead of comparable criteria that exclude the cognitively impaired from consideration.

The "CI or BP" criterion is the most liberal of the three cognitive impairment criteria included in the estimates; it clearly yields the highest estimates of all the measures. However, this particular criterion may result in an overestimate of the cognitively impaired population because of the way in which the behavior problem factor figures into the criterion. For example, under the 2+ ADLs *or* CI *or* BP rule a person without any ADL disabilities, who is not considered cognitively impaired according to the CI criterion, but who compulsively steals, would be deemed eligible. A person with this particular profile may not be an appropriate candidate for home care services, and including such persons in an eligibility pool may result in misspecifying the targeted population, even under very liberal targeting policies.

A more conservative approach would be to define cognitive impairment solely in terms of evidence of cognitive impairment, as exemplified by the CI criterion. With this criterion, fewer individuals would fall into the eligibility pool. Although using the cognitive impairment criterion instead of the CI *or* BP criterion does lower the estimates, the decrease is only on the order of 0.2% to 0.5%, or 60 000 to 150 000 fewer eligible persons nationwide, depending upon the exact ADL criteria invoked and the definition of disability used.

This approach, though more conservative, is still subject to criticism. A score on a cognitive impairment test, or even a diagnosis of Alzheimer's disease, does not necessarily correspond to a need for home care. The target population for home care services should probably not include persons for whom organicity has not yet impeded independent functioning of ADLs or presented a threat to the safety of the individual. This criticism has led to the suggestion that eligibility for home care services for cognitively impaired persons be linked to more specific evidence of the need for care. The CI+ criterion responds to this suggestion by requiring that eligibility for services be evidenced by an SPMSQ score indicating cognitive impairment (or a cognitive impairment–related diagnosis) *and* some evidence of the need for care or oversight. Such care or oversight might be required because of (1) one or more ADL disabilities *or* (2) a disability in one of the three cognitively oriented IADLs (money management, medication management, or telephoning) *or* (3) display of behavior problems.

The CI+ criterion is undoubtedly the most restrictive of the three cognitive impairment criteria. For example, 6.8% of the nation's elderly would be service-eligible under the 2+ ADLs (active) *or* CI *or* BP criterion, and 6.5% under the 2+ ADLs *or* cognitive impairment criteria, but only 4.8% under the 2+ ADLs *or* CI+ criterion. Yet this 4.8% estimate is substantially higher than would result from the same criterion without the cognitive impairment component added. This translates into an additional 450 000 eligible persons under the 2+ ADLs *or* CI+ criterion who are eligible because of the cognitive impairment component alone.

TABLE 1—Number of Community Elderly (in Thousands) Aged 65+, by Alternative Activities of Daily Living (ADL) Disability and Cognitive Impairment Criteria, 1990

No. ADLs[d]	No. Meeting ADL Criteria	No. Meeting ADL or Cognitive Impairment Criteria: CI or BP[a]	CI[b]	CI+[c]
A. ADL Disability Criterion: Active Assistance Only				
1+	1837	2701	2606	2114
	(6.1)	(9.0)	(8.7)	(7.0)
2+	1007	2056	1947	1458

	(8.2)	(10.6)	(10.3)	(9.0)
3+	1561	2490	2390	1946
	(5.2)	(8.3)	(7.9)	(6.5)

Note. Numbers in parentheses represent the percentage of the community-residing population aged 65 years and older who meet the criteria.

[a]Score of 5+ on Short Portable Mental Status Questionnaire (SPMSQ) or cognitive impairment–related diagnosis or behavior problem (BP).

[b]Score of 5+ on SPMSQ or cognitive impairment–related diagnosis.

[c]CI plus behavior problems or CI plus either 1+ ADL or disability in money management, telephoning, or medication management.

[d]There are five core ADLs: bathing, dressing, toileting, transferring, eating. The numbers in this column indicate how many of these activities with which the individual needs help.

Discussion

In this study, we have demonstrated how various eligibility criteria can be used to derive estimates of the disabled elderly population living in the community, taking into account those in need of services because of cognitive impairment. We have shown how these various criteria affect the size of the population that would be made eligible for benefits under alternative definitions of functional disability and cognitive impairment.

It must be recognized that these estimates are derived from survey data, and incentives for survey respondents to overstate their disabilities are minimal. Survey respondents, unlike program applicants, receive no benefit from exaggerating their disability. In fact, there is some evidence that survey respondents may underestimate their disability levels.[5] Thus we would expect some increase in self-reported disability if persons were applying for services and knew that their receipt of service was contingent upon a disability measure. Additionally, when service eligibility is predicated on the need for *human* assistance in performing ADLs, there may be a disincentive to substitute assistive devices for human help, thus rendering the impaired more dependent than necessary and also jeopardizing the development of new technologies for fostering independence.

Nonetheless, the estimates presented in this paper demonstrate how substantially different estimates of the disabled elderly population with and without cognitive impairment, can be generated by employing varying definitions of disability. The use of more stringent or more liberal eligibility criteria for home care services will have dramatic effects on the number of elders who would qualify for services. The most obvious implication is that the specific eligibility criteria employed in legislation to expand federally financed home care services will be major factors in determining the ultimate costs of such an expansion. A second implication is that unless the eligibility criteria designated in the legislation are specific in their definitions, the number of persons who will actually qualify for benefits will depend largely upon how the general language of the legislation is interpreted in regulatory and administrative procedures during program implementation. This could lead to considerable discrepancy between the intent of the legislation and its actual implementation.

Definitions of disability using measures of ADL impairment have become popular mechanisms for allocating home care resources under proposed federal legislation. However, the need for publicly financed home care depends upon a variety of factors, not just one's level of disability. Financial need is an obvious factor, and one that is also built into many legislative initiatives. However, it is also true that the elderly adjust to their disabilities through a multitude of adaptive behaviors, just as nonelderly persons with disabilities do. In addition, many elderly persons have access to support from family and friends that can augment the formal provision of services. Given the variety of factors that contribute to the need for home care, should a federal entitlement program for home care services, based solely on standardized measures of disability, be implemented? What role, if any, should the availability of family and friends, as well as financial status, play in eligibility determination and service allocation?

In any case, it is apparent that the establishment of criteria to determine which elderly persons with disabilities should be eligible for publicly funded home care and which should not is not a simple matter. In this context the question must be raised whether it is possible to enact federal legislation that would ensure that benefits are allocated in an equitable manner according to true need. Unlike access to publicly financed acute care services, which is determined primarily by physicians, access to expanded federal home care benefits will require policy makers to establish relatively specific decision rules about who is eligible for benefits and who is not.

Acknowledgments

Funding for this study was provided under contract HHS-100-88-0041 from the Department of Health and Human Services, Office of the Assistant Secretary for Planning and Evaluation, Division of Disability, Aging, and Long-Term Care.

We would like to acknowledge the assistance of William D. Spector, PhD, and Peter Kemper, PhD, from the Agency for Health Care Policy and Research for providing some of the analytic files used in these analyses. We would also like to thank Sidney Katz, MD, for his review of an earlier draft of this manuscript. The technical assistance provided by Karen Koch of Social and Scientific Systems and Sean Kennedy of SysteMetrics is also greatly appreciated.

Postmarketing Surveillance Study of Permethrin Creme Rinse

Elizabeth B. Andrews, PhD, Michael C. Joseph, MD, MPH, Mark J. Magenheim, MD, MPH, Hugh H. Tilson, MD, DrPH, Peggy A. Doi, and Margaret W. Schultz, MPH

ABSTRACT

Background. An observational, epidemiological study was undertaken to evaluate the safety of permethrin 1% creme rinse (Nix™) for treatment of head lice infestations.

Methods. Thirty-seven local public health departments enrolled a total of 38 160 patients for 47 578 treatments with permethrin or other pediculicides from September 1, 1986, through January 31, 1988. Follow-up safety information was collected between 7 and 14 days following treatment via return visit or telephone contact.

Results. One hundred three adverse events were reported among 41 955 evaluable treatments. The rates of reported adverse events were 2.2 per 1000 treatments among permethrin treatments, 3.4 per 1000 treatments among lindane treatments, and 1.5 per 1000 treatments among other over-the-counter treatments. No serious, unexpected adverse events were detected in the 18 950 patients treated with permethrin.

Conclusions. This study confirmed the safety profile of permethrin in conditions of general use, as seen in clinical trials. Postmarketing safety monitoring in public health departments of drugs used to treat public health conditions was shown to be feasible. (*Am J Public Health.* 1992;82:857–861)

Introduction

Infestation with head lice continues to be a public health concern in the United States, particularly among schoolchildren. Surveys indicate that approximately 2.6 million households (or 2.8 million individuals) experience an outbreak of head lice each year, and studies by the Centers for Disease Control between 1973 and 1974 found an overall prevalence of head lice of approximately 8% in schoolchildren (grades K to 8).[1–3]

Permethrin 1% creme rinse, hereafter referred to as permethrin, contains the synthetic pyrethrin permethrin (a pyrethroid). It has been available by prescription for head lice treatments since June 1986. Before its marketing, the only available pediculicides were prescription compounds containing lindane (Kwell and generic products) and over-the-counter (OTC) products, most of which contain pyrethrins (A–200®, RID®, and others). Since completion of this study, permethrin has become available OTC.

In clinical studies of over 3500 patients, the only expected adverse drug experience associated with permethrin was local irritative symptoms, which ranged in frequency from 2.1% to 5.9%. Many of these symptoms were thought to be the result of the lice infestation.[4–6]

This postmarketing safety study provided the principal new data on which the conversion of permethrin from prescription to OTC status was based.[7] It used recognized epidemiological methods both to assess the short-term safety of permethrin for general use in the treatment of head lice and to identify, document, and assess rare but medically important events following treatment. It was not intended to compare effectiveness of the different pediculicides.

Methods

In this observational, epidemiological safety study, public health departments dispensed permethrin or another pediculicide, counseled about treatment in the customary methods, and followed each patient between 7 and 14 days after treatment via return visit or telephone call to identify any subsequent adverse clinical events.

Health departments developed treatment allocation schemes to ensure that each diagnosed individual had essentially the same chance of being treated with permethrin or another pediculicide. This quasi-randomization system included such measures as assigning treatment according to day of the week patient was diagnosed with head lice infestation (there being no a priori reason to believe that patient mix varied by day of week), and alternating treatment choice by patient or family group. Analyses of baseline characteristics, by site, were conducted to evaluate the adequacy of the allocation schemes.

This paper was submitted to the Journal May 11, 1990, and accepted with revisions July 10, 1991.

Health departments enrolled infested school-aged children and their family members ages 2 years or above with head lice infestation. Pregnant women and persons with a history of allergic reactions to pyrethrins were excluded.

The existing staff of 37 public health departments in 12 states were collaborative study investigators (see acknowledgement). During the treatment period (September 1, 1986, to January 31, 1988), 38 160 patients were enrolled for 47 578 treatments. Four sites in Michigan enrolled 13% of all patients, 10 other sites in 10 states enrolled 27%, and 23 sites in Florida enrolled the remaining 60%. The median enrollment for individual sites was approximately 650 patients (ranging from 65 to 3293).

In July 1986, the State of Florida Institutional Review Board (IRB) of the Department of Health and Rehabilitative Services and an independent, federally qualified IRB of the fourth-largest hospital in Florida (an 862-bed public facility with substantial research activities) reviewed and approved the full research protocol, including methods and detailed provisions for the protection of human subjects, for all participating Florida study sites. All participating health departments were provided permethrin free of charge and were reimbursed for study expenses, including the cost of obtaining other pediculicides, according to negotiated budgets. Further details of the process of designing and implementing a network of collaborating public health clinic sites will be described in another paper.

Treatment and Assessment Plan

At enrollment, patient initials, birth date, sex, ethnic group, history of allergic problems, name of the pediculicide dispensed, and previous enrollment in the study were recorded.

Follow-up information was solicited using a common protocol. If patients did not return to the health department, a telephone callback system was used to gather the information. When an adverse event was reported, symptoms, concurrent medications and illnesses, and course of required treatment, if any, were solicited. An adverse event was classified as "medically important" if medical consultation was actually sought or if the event was likely to require clinical monitoring, whether or not any medical consultation was obtained. Events of unspecified or ambiguous severity were classified as medically important.

Information was obtained on treatments for 38 180 patients. Only those treatments for which follow-up was complete (41 955 treatments of 34 275 patients) were used in the analysis. The proportion of patients available for follow-up did not vary by treatment type, and their baseline characteristics did not differ from those of patients lacking follow-up.

Classified by pediculicide exposure, 18 950 (55.3%) patients received permethrin, 10 155 (29.6%) received lindane products, and 5170 (15.1%) received one of the 28 different OTC products. OTC products included RID® (3171 patients), Pyriny!® (699 patients), and an assortment of similar pediculicides. Lindane and OTC groups were analyzed separately because of differences in their potency and safety profiles.

Sample Size and Power

The sample size was sufficient to detect a threefold increase in the incidence of an adverse event that had an expected frequency of 1 in 1000, with a 95% significance level when comparing the group treated with permethrin with the group treated with lindane, and 80% power and a 95% significance level when comparing the permethrin group with the group treated with OTC products. Calculations were based on the binomial distribution.

Results

Participant Characteristics

The distribution of patients by age, sex, ethnic group, and allergy history was similar among the three treatment groups (Table 1). No significant differences were seen across sites (data available upon request). The age distribution of the study participants was bimodal: 57% were between 2 and 15 years of age and 25% were between 21 and 55 years of age. Eight percent of the participants reported a history of allergies or allergic conditions.

Analysis Using All Treatment

Data were first analyzed using all treatments for which follow-up information was obtained (n = 41 955). Because the retreatment experience might be dependent on the outcome of the first study treatment, an analysis of data restricted to the first study treatment was also completed (n = 34 275).

Of the 41 955 evaluable treatments, there were 103 reported adverse events (2.5 per 1000), 2.2 per 1000 (95% CI: 1.6, 2.9 per 1000) after permethrin treatment, 3.4 per 1000 (95% CI: 2.5, 4.6 per 1000) after lindane treatment, and 1.5 per 1000 (95% CI: 0.7, 2.7 per 1000) after OTC treatment. The risk difference when comparing permethrin with lindane was –1.2 per 1000 (i.e., 1.2 fewer problems per 1000 permethrin treatments; 95% CI: –2.4, –0.05). The risk difference when comparing permethrin with OTC treatments was 0.7 problems per 1000 treatments (i.e., 0.7 more problems per 1000 permethrin treatments; 95% CI: –0.4, 1.8 per 1000).

Consistent with results from clinical trials in the United States, all three treatment groups reported pruritus and rash more frequently than they reported other adverse events. Eight events were considered medically important. When the statistical analysis was restricted to those events, or to events for which medical attention was sought, there were no significant differences between the permethrin group and either of the comparison groups. In the permethrin group, five adverse events, summarized below, were medically important. Two of the patients were not treated with permethrin themselves but came into contact with a treated family member.

Case P1: A 16-year-old girl with no previous history of allergy experienced breathing difficulty while her sister was being treated with permethrin. The episode subsided after the girl left the treatment room.

Case P2: A 34-year-old woman with a history of drug allergies experienced mild nausea and moderate to severe shortness of breath that lasted about 4 hours. The patient had been taking Inderal® (propranolol) (12 mg daily).

Case P3: A 10-year-old girl with a history of asthma and food allergies experienced arm shaking and stuttering that lasted less than a minute and did not recur. The patient did not require a medical visit. She had used the pediculicide A-200® on two occasions, 10 days and 6 days before treatment with permethrin.

Case P4: A 35-year-old woman (mother of P3) with a history of food allergies experienced two incidents of arm shaking for about 40 seconds and some skin irritation. The patient did not have a medical visit for these events. The Health Department physician stated that the arm shaking was probably due to the patient's steady use of her arms in applying 10-minute massages to three individuals on the same day.

[a]OTC = over-the-counter products.
[b]Data on sex missing for 82 patients.
[c]Data on ethnic group missing for 97 patients.

Case P5: A 23-year-old woman with no previous allergy history experienced a swollen face beginning 1 day after treatment and lasting 1 week. She required medical treatment. The patient reported that the adverse event could have been caused by a new facial soap and that she did not attribute it to the permethrin treatment.

Among patients treated with lindane, three adverse events were judged medically important.

Case L1: A 31-year-old woman with no previous history of allergies experienced "extreme" blurred vision that lasted 7 days and did not recur. The event required a medical visit.
Case L2: A 39-year-old man with an extensive history of allergies and asthma experienced moderate respiratory irritation that lasted 18 hours. No medical visit was required.
Case L3: A 28-year-old woman with a history of asthma, hay fever, and other allergies experienced moderate difficulty in breathing for 24 hours following treatment. An OTC bronchodilator was used to treat the episode, and no medical visit was required.

Among patients treated with OTC pediculicides, there were not medically important adverse events.

Analysis Using First Treatment per Patient

Among the 34 275 first study treatments, there were 87 reported adverse events, 2.4 per 1000 (95% CI: 1.8, 3.2 per 1000 patients) after permethrin treatment, 3.5 per 1000 (95% CI: 2.5, 4.9 per 1000 patients) after lindane treatment, and 1.0 per 1000 (95% CI: 0.3, 2.3 per 1000 patients) after OTC treatment. The risk difference when comparing permethrin with lindane was –1.1 per 1000 (i.e., 1.1 fewer problems per 1000 patients treated with permethrin; 95% CI: –2.5, 0.2 per 1000). The risk difference when comparing permethrin with OTC patients was 1.5 events per 1000 patients (i.e., 1.5 more problems per 1000 patients treated with permethrin; 95% CI: 0.4, 2.6 per 1000). When the analyses were restricted to adverse events that appeared to be medically important or for which medical consultation was sought, there were no statistically significant differences between the permethrin group and either the lindane or the OTC group.

Stratified analyses were performed to determine if the different reporting rates for adverse events were caused by small differences between treatment groups in age, sex, ethnicity, or allergy status. The prior findings were not altered substantially when these factors were controlled (data available upon request).

Analyses were also performed across all exposure groups to assess the relationship between patient characteristics and the reporting of adverse events following treatment. When all pediculicidal exposure was combined (Table 2), patients with a history of allergy were more than four times as likely (8.4 per 1000) to report an adverse event after treatment than were patients without a prior allergy history (2.0 per 1000). The risk difference was 6.4 per 1000 (95% CI: 2.9, 9.8 per 1000). In addition, females were 2.4 times as likely (3.4 per 1000) to report an adverse event than males (1.4 per 1000). The risk difference was small (2.0 per 1000 patients; 95% CI: 0.98, 3.00 per 1000).

Discussion

The overall rate of adverse events reported after treatment in this study was very low—between 1.0 and 3.5 events per 1000 patients. This rate of events was approximately one tenth that seen in more

closely monitored experimental trials in the United States. Because this postmarketing epidemiological study sought primarily to discover rare, serious, and unexpected adverse events, data collection was not designed to assess or confirm frequent and less serious events. Therefore, the low reporting rate of common, expected events observed in this study was predictable.

Although adverse events might have been underreported, there was no incentive for participants to report preferentially or underreport problems by treatment group. However, it is acknowledged that such bias could not have been strictly controlled in this unblinded, nonrandomized trial. The perceived risk of treatment with each product by patients, parents of patients, and medical staff, or the perception that this was a "permethrin study," could have introduced bias in reporting problems.

When the rate of overall reported problems among the permethrin treatments was compared with the rates among the lindane and OTC groups, there was a consistent pattern. The permethrin patients reported a rate of adverse events lower than that of the lindane patients and higher than that of the OTC patients. Observed differences, however, were small. Because the sample size was so large, even small and perhaps unimportant differences would be statistically significant. Moreover, risk differences observed in this study were small, on the order of one per thousand patients or treatments.

There were no significant differences between permethrin and either the lindane or the OTC comparison group when the analysis was restricted to those problems that were medically important. The most important adverse event was difficulty in breathing, which was reported in 4 patients (2 of 18 950 permethrin patients and 2 of 10 155 lindane patients), 3 of whom had a previous history of allergies.

No serious or unexpected adverse event was detected in association with permethrin despite a sample size adequate to detect such an event at a rate of 1 per 10 000 treatments with 85% probability.

Although considerations for patient safety and methodology were paramount in the study design and analysis, attention to feasibility and to patient and provider acceptability were also important practical objectives. Careful attention not to interfere unduly with normal patient care activities imposed several limitations on study design (and on data quality to a minimal degree). Strict randomization of pediculicide treatments was not feasible, and the choice of allocation schemes varied among and within participating local public health agencies. However, once determined, individual allocation schemes were reported to have been followed, and there was no evidence of systematic bias in overall treatment allocation, given that summary analyses indicated comparable allocations among all treatment options. Additional analyses comparing patient characteristics and results by site also showed no differences.

Although complete follow-up was not attainable for 10% of enrolled patients, there is no a priori reason to believe that the patients lacking follow-up information experienced different outcomes from those experienced by patients who provided such information. Analyses of baseline characteristics showed that the two groups were not different. Furthermore, because the local health department is often an important source of medical care in the community, it is likely that significant problems among patients without explicit follow-up information would have come to the attention of the responsible health department.

This public-private collaborative study approach demonstrates the ability to gather relatively basic, yet clinically important safety information on an extremely large and diverse study population through a public health field research stratagem without unduly compromising safety or data quality. □

Acknowledgments

This study was funded by research grants from the Burroughs Wellcome Company. The authors wish to thank the participating health departments as well as Kathy Schoeffler, Linda Wastila, and Anita Blanchard for their assistance in data management and quality assurance. Call for Papers for Symposium on Analysis of Soils Contaminated with Petroleum Constituents

Original papers are needed for the Symposium on Analysis of Soils Contaminated with Petroleum Constituents, sponsored by the American Society for Testing and Materials (ASTM) Committee D-18 on Soil and Rock, in cooperation with the American Petroleum Institute. The symposium will be held June 24 to 25, 1993, in Atlanta, Ga, and will examine the existing technology used by scientists and engineers to measure and evaluate soil material that has become contaminated with organic derivatives of petroleum hydrocarbons or unrefined petroleum.

Papers that address these topics are solicited:

- Contaminated soil sample collection
- Volatile organic compound analysis of soil contaminated with petroleum constituents
- Semi-volatile organic compound analysis of soil contaminated with petroleum constituents
- Pesticide and PCB analysis of soil contaminated with petroleum constituents
- "Total" preparation/analyses of soil contaminated with petroleum constituents: total petroleum hydrocarbons, total organic carbon, total halogenated carbon, oil, and grease
- Contaminated soil data interpretation and statistical analysis

Prospective authors are asked to submit a title, a 250- to 300-word abstract, and an ASTM paper submittal form by *June 23, 1992,* to Dorothy Savini, Symposia Operations, ASTM, 1916 Race Street, Philadelphia, PA 19103-1187; tel. (215) 299-5413. Sending your abstract by fax is not encouraged because copies do not reproduce well. Paper submittal forms are available from Ms. Savini or from the symposium chairman.

A special technical publication based on the symposium proceedings is anticipated by ASTM. For more information contact Symposium Chairman Tracey O'Shay, Gordon and Lawton, P.O. Box 80072, Austin, TX 78727-0072; tel. (512) 475-2302; or Co-Chairman Keith Hoddinott, US Army Environmental Hygiene Agency, attn: HSHB-ME-SR, Aberdeen Proving Grounds, MD 21010-5422; tel. (301) 671-2953.

Committee D-18 is one of 132 ASTM technical standards-writing committees. Organized in 1898, ASTM is one of the largest voluntary standards development systems in the world.

First-Year Impact of the 1989 California Cigarette Tax Increase on Cigarette Consumption

Robert L. Flewelling, PhD, Erin Kenney, PhD, MPH, John P. Elder, PhD, MPH, John Pierce, PhD, Michael Johnson, PhD, and Dileep G. Bal, MD

ABSTRACT

We employed a time series design to evaluate the impact of the 1989 California cigarette tax increase on cigarette consumption in California. Adult per capita consumption data from 1980 to 1990 were analyzed for California and the United States. Trend data indicated a sharp drop in California cigarette consumption coincident with the tax increase. Time-series regression analyses support this observation, and suggest that a 5% to 7% decline in consumption is attributable to the tax increase. (*Am J Public Health.* 1992;82:867–869)

Introduction

With the passage of the voter-initiated California Proposition 99, the state excise tax on cigarettes was increased by 25 cents per package, effective January 1, 1989.[1] Although the initiative earmarked a percentage of the new revenues for tobacco use control, medical care, and tobacco-related research,[2] excise taxes have also been recognized as having potential public health benefits by reducing cigarette consumption.[3–7] The purpose of this study was to estimate the impact of the 1989 tax increase on cigarette consumption in California.

Methods

Cigarette consumption data were derived from state government records of cigarette excise tax revenues.[8] Quarterly adult per capita consumption was computed by dividing the total number of packs of cigarettes taxed by the estimated population over age 17. Quarterly estimates of the adult population were interpolated from yearly estimates published by the US Census Bureau.[9,10] Quarterly prices for cigarettes were interpolated from annual (November) estimates[11] and adjusted for inflation.

A quasi-experimental multiple time series design was used to analyze consumption data from 1980 through the end of 1990. This period offers a relatively stable baseline against which extraneous effects can be quantified. Consumption data from California and the United States were first plotted to visually assess any change in the consumption trends. Time-series regression analyses were conducted to assess the size and significance of the impact of the tax increase. The regression models controlled for the influence of changes in the real price of cigarettes, and for other factors known to influence cigarette distribution and sales. Because of multicollinearity among the predictor variables, three alternative regression models were used: (1) an ordinary least squares (OLS) model with all relevant variables included; (2) an OLS model with an extraneous, prespecified coefficient for the real price of cigarettes; and (3) a ridge regression model with all relevant variables included. The extraneous price coefficient in the second model was based on a −0.4 price elasticity of demand for cigarettes and for consumption and price levels just prior to the tax increase.

Results

Quarterly per capita consumption trends from 1980 to 1990 for California and for all other states combined are plotted in Figure 1. Immediately apparent are the overall lower consumption rate in Califor-

Editor's Note. See related editorial on p 785 of this issue.

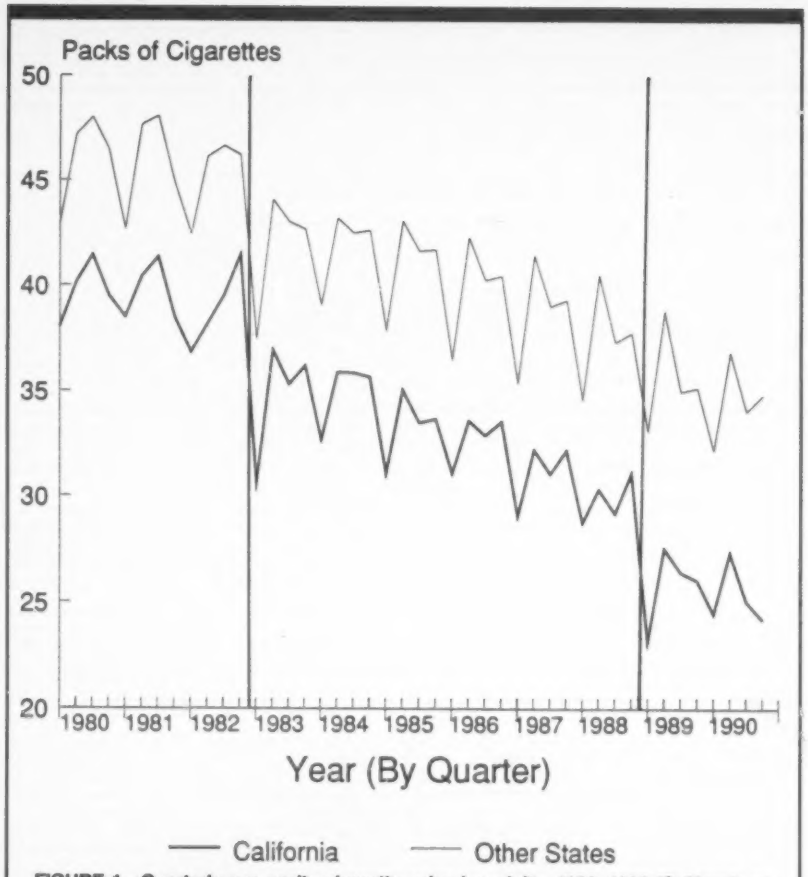

FIGURE 1—Quarterly per capita cigarette sales by adults, 1980–1990 (California vs United States)

TABLE 1—Annual Percentage Decline in Adult per Capita Cigarette Consumption for California and Other States, 1983–1990

	California	Other States
Years before 1989		
1983 to 1984	0.93	1.11
1984 to 1985	4.99	1.86
1985 to 1986	1.56	2.91
1986 to 1987	5.10	2.77
1987 to 1988	4.27	3.16
Mean	3.40	2.44
Year of tax increase		
1988 to 1989	9.30	5.38
Years after 1989		
1989 to 1990	4.30	2.88

Note. Annual percentage declines were computed by averaging the declines for each quarter over the entire year. Quarters immediately before or after the 1983 federal tax increase and (for California) the 1989 tax increase were excluded from calculations.

nia than in all other states, the seasonal patterns by quarter, and a general downward trend in consumption. The 1983 federal tax increase and the 1989 California tax increase are indicated by vertical reference lines. There was a noticeable decline in consumption, which appears to be permanent, at the time of the federal tax increase. As expected, the California tax increase apparently affected consumption at a time exactly coincident with the implementation of the increased tax. Positive pretax and negative posttax consumption spikes, presumably due to stockpiling, are apparent for California and the United States in 1983, and for California in 1989.

The average decline in consumption from 1988 to 1989 was 9.3%, whereas the average yearly decline in the 5 years prior to the tax increase was 3.4% (Table 1). Assuming that the pretax rate of decline would have continued in the absence of the tax increase, the excess drop in consumption following the tax increase may be estimated as the difference between the two rates, or 5.9%. The decline in other states was also somewhat larger than observed in previous years and may be due to sizable tax increases in several other large states.

Table 2 presents the results of the three regression models for predicting quarterly adult per capita consumption in California. The main variable of interest is CALTAX, the dummy variable representing all quarters subsequent to the California tax increase. The coefficients for this variable estimate the overall drop in quarterly per capita consumption coincident with the 1989 California tax increase, when other known effects on cigarette consumption are controlled. The first two models produce very consistent parameter estimates; the third model produces a somewhat larger estimate. Taken together, the results suggest that a drop in per capita consumption of between about 1.5 and 2.0 packs per capita (quarterly) may be attributed to, or is at least coincident with, the 1989 tax increase. This translates to a 5% to 7% drop in per capita consumption from the 1988 level. When similar models were run for all other states combined, no statistically significant effect for CALTAX was found.

Discussion

The present analysis supports the conclusion that the implementation of the 1989 cigarette excise tax increase in California did have a significant impact on adult per capita cigarette consumption as approximated by tax-paid sales. The 5% to 7% decline in consumption derived from the regression models was consistent with the unadjusted trend data. Because the regression models control for the influence of the real price of cigarettes and base the estimated effect on all quarters subsequent to the tax increase, they appear to provide a more valid method for estimating the impact of the tax increase.

An issue that cannot be entirely resolved with the available data concerns the long-term effects of the tax increase. Although the regression models assume a one-step, permanent drop in consump-

tion, the long-term impact of the tax increase is uncertain. Even with additional data, estimating long-term effects is tenuous because of potential confounding forces, such as price, public education, and societal trends, that also influence changes in smoking behavior.

It is possible that the true impact of the California tax increase is slightly lower than the rate of 5% to 7% suggested by this study. Consumption trends in neighboring states indicate that a small percentage of the decline in California may be due to increased interstate bootlegging. Also, although not statistically significant, the unusually large decline in consumption between 1988 and 1989 in other states suggests that other influences besides the tax increase may also have been operative in California.

The estimated impact of the 1989 tax increase represents a price elasticity of between −0.25 and −0.35 and is somewhat less than previous studies on the price elasticity for cigarettes would have predicted. As the social acceptability of smoking continues to wane, smokers may be increasingly resistant to efforts that encourage cessation, including price increases. Thus, a broad array of educational strategies and policy mechanisms will be required to ensure that progress toward a smoke-free society is maintained. (The full report, containing a detailed description of the analytic method and results, is available from the authors upon request.) □

TABLE 2—Regression Coefficients for Predicting Quarterly Adult per Capita Cigarette Consumption in California and Other States, 1980–1990

Variable[a]	Model: Full	Model: Extraneous REALPC[b]	Model: Ridge[c]
CALTAX[d]	−1.46**	−1.50**	2.08
REALPC	−0.11*	(−0.10)	−0.15
UAR	−0.24***	−0.25***	−0.15
Q2DUM	2.86***	2.86***	2.21
Q3DUM	2.62***	2.62***	1.53
Q4DUM	2.53***	2.53***	1.27
PREFED	3.86***	3.85***	3.64
POSTFED	−3.28**	−3.36***	−2.70
PRETAX	1.40	1.39	0.49
POSTTAX	−2.22*	−2.18*	−2.86
R^2	.96	.97	...
Durbin-Watson	2.53	2.52	...

[a]CALTAX is the dummy variable indicator for all quarters since January 1, 1988; REALPC is the estimated real price of cigarettes (excluding the 25-cent increase due to the 1989 tax increase); QUARTER is the quarter number (starting with the first quarter of 1980), used to capture the overall downward linear trend in consumption; Q2DUM, Q3DUM, and Q4DUM are dummy indicators for second, third, and fourth quarter of each year to control for seasonal variation in wholesale distributions; and PREFED, POSTFED, PRETAX, and POSTTAX are dummy variables to capture the pre- and posttax increase sales spikes associated with the 1983 federal and 1989 state excise tax increases.
[b]Extraneous REALPC model is an OLS model with an extraneous, prespecified coefficient for the real price of cigarettes (based on −0.4 price elasticity and for consumption and price levels just prior to the tax increase).
[c]Parameter estimates for $k = .30$.
[d]For each model, the coefficient for the variable CALTAX reflects the average sustained change in quarterly adult per capita consumption associated with the 1989 tax increase.
*$P < .05$; **$P < .01$; ***$P < .001$. (Significance levels not available for ridge regression models.)

Drug Use and Suicide Ideation and Behavior among North Carolina Public School Students

W. Michael Felts, PhD, Thomas Chenier, PhD, and Robert Barnes, EdD

ABSTRACT

We used data from 3064 respondents to the 1990 North Carolina Youth Risk Behavior Survey to examine the relationship between adolescent drug use and suicide ideation and behavior. Principal components analysis followed by varimax rotation was performed separately on the drug use and suicide items. Correlation coefficients computed between the two sets of factor scores and comparison of mean drug use factor scores revealed that drug use, particularly of crack/cocaine, was related to increased suicide ideation and behavior. (*Am J Public Health.* 1992; 82:870–872)

Introduction

Suicide, now the second leading cause of death among US youth aged 15 to 19,[1] is a preeminent concern among health professionals seeking to improve the health status of adolescents in the United States.[2] The design of effective intervention strategies to address this problem depends on the identification of risk factors related to suicide ideation and behavior. Among the risk factors currently acknowledged to be in some way linked to adolescent suicide are previous suicide attempts, illness, family violence, precipitous life events, and substance abuse.[3]

The purpose of this study was to determine if a relationship existed between suicide ideation and behavior and substance abuse among adolescents attending North Carolina public secondary schools and, if so, to delineate the nature of that relationship.

Methods

These data were collected as part of a larger study of health risk behaviors of North Carolina public school students.[4] The Youth Risk Behavior Survey (YRBS)[5] was administered during May 1990 to students in 9th- and 12th-grade classes that had been randomly selected using a self-weighting two-stage cluster sampling procedure. The survey instrument consisted of 61 forced-choice items, 4 of which addressed demographic questions; the remaining 57 items dealt with student behavior related to (1) violence; (2) tobacco, alcohol, and drug use; (3) exercise; (4) nutrition; and (5) intentional and unintentional injury.

The responses were randomly divided into two subsamples. For each subsample, responses to 13 questions dealing with drug use and 4 questions about suicide ideation and behavior were analyzed. Descriptive statistics were generated for the 17 questions of interest, and principal component factor analysis, with varimax rotation, was applied separately to the drug use and suicide questions.[6] Relationships between the extracted factors were then determined through correlational analysis and comparisons of mean factor scores. Because the results of the cross-validation analyses were identical, all data were pooled to generate the reported results.

Results

The validity of the self-report data was substantiated by comparison with results of recent surveys of comparable populations. Drug use data were compared with those collected approximately 1 year earlier in the statewide Alcohol and Drug Defense (ADD) survey.[7] Because no previous statewide survey of suicide ideation and behavior had been conducted, these results were compared with those of the National Adolescent Student Health Survey.[8] Although these comparisons were imprecise because of differences in item wording and grade range groupings from which data were collected, the North Carolina YRBS (NCYRBS) data closely paralleled the results of the two comparison surveys. For example, 2.3% of the students in grades 7 through 12 reported having used cocaine within the previous 30 days in the ADD survey, compared with 2.4% of 9th and 12th graders in the NCYRBS. In the ADD survey, 13.6% of the students in grades 7 through 12 reported having used marijuana within the previous 30 days; this response was given by 11.0% and 14.0% of 9th and 12th graders, respectively, in the NCYRBS. Thirty-three percent of the NCYRBS respondents reported having thought about suicide and 4.5% reported that they had actually made a suicide attempt in the 12

TABLE 1—Results of Principal Components Analysis with Varimax Rotation of Response to Thirteen Drug Use Items

Question	Factor 1 Cocaine/Crack	Factor 2 Alcohol	Factor 3 Marijuana	Factor 4 Needle Drugs
During your life, on how many occasions have you used cocaine in any form (including powder, crack, or freebase)?	.91	...	...	...
During the past 30 days, on how many occasions have you used cocaine in any form (including powder, crack, or freebase)?	.91	...	...	...
How old were you when you used cocaine in any form (including powder, crack, or freebase) for the first time?	−.74	...	...	...
During your life, on how many occasions have you used the *crack* or *freebase* form of cocaine?	.88	...	...	...
During the past 30 days, on how many occasions did you drink alcohol (including wine, wine coolers, beer, liquor, or mixed drinks)?	...	.88	...	...
During the past 30 days, how many times did you have five or more drinks on one occasion? (A "drink" is a glass of wine, a wine cooler, a bottle or can of beer, a shot glass of liquor, or one mixed drink.)	...	.81	...	...
During your life, on how many occasions did you drink alcohol (including wine, wine coolers, beer, liquor, or mixed drinks)?	...	.85	...	
How old were you when you had your first drink of alcohol (other than a sip)?	...	−.77	...	...
During your life, on how many occasions have you used marijuana?	...	...	.86	...
During the past 30 days, on how many occasions have you used marijuana?	...	...	.65	...
How old were you when you used marijuana for the first time?	...	...	−.81	...
During your life, on how many occasions have you used any other type of illegal drugs such as LSD, PCP, MDMA, "Ecstasy," mushrooms, speed, or heroin?	...	...	.58	...
During your life, have you ever injected (shot up) any drug not prescribed by a doctor, such as steroids, cocaine, amphetamines, or heroin?	...	...	...	.92

Note. Ellipses indicate that factor loading is less than 0.5 in magnitude.

months prior to survey administration. Approximately 30% of respondents (aged 12 to 19) to the NASHS reported to have seriously thought about committing suicide, with 18% of girls and 11% of boys reporting to have actually attempted suicide.[8] Detailed tables of the North Carolina YRBS data are available from the authors upon request.

Table 1 contains results of the exploratory factor analysis of the 13 drug use items. On the basis of observed eigenvalues, four factors were extracted by means of a principal components algorithm and then subjected to varimax rotation. Factor 1 (cocaine/crack) is made up of four questions dealing with cocaine and crack use. Factor 2 (alcohol) comprises four questions dealing with patterns of alcohol use. Factor 3 (marijuana) is composed of three questions dealing with marijuana use and a single item dealing with the use of a variety of illicit substances including LSD, heroin, and mushrooms. Factor 4 (needle drugs) consisted of a single question dealing with use of injectable drugs. Factor analysis of the four suicide questions yielded a two-factor solution (Table 2). Factor 1 is associated with suicide ideation and intention and factor 2 with suicide behavior and the severity of its outcome.

TABLE 2—Results of Principal Components Analysis with Varimax Rotation of Responses to Suicide Ideation/Behavior Items

Question	Factor 1 Suicide Ideation	Factor 2 Suicide Behavior
During the past 12 months, have you ever *seriously* thought about attempting suicide?	.89	...
During the past 12 months, did you make a specific plan about how you would attempt suicide?	.84	...
During the past 12 months, how many times did you actually make a suicide attempt?	...	.76
If you attempted suicide during the past 12 months, did that attempt result in an injury or poisoning that had to be treated by a doctor or nurse?	...	.93

Note. Ellipses indicate that factor loading is less than 0.5 in magnitude.

Correlation coefficients computed between the drug factor and suicide factors were as follows: suicide ideation/intention with cocaine/crack, $r = -.08$ ($P = .0001$); with alcohol, $r = -.16$ ($P = .0001$); with marijuana, $r = -.10$ ($P = .0001$); with needle drugs, $r = .08$ ($P = .0001$); and suicide behavior/severity with cocaine/crack, $r = .32$ ($P = .0001$); with alcohol, $r = .08$ ($P = .0001$); with marijuana, $r = .11$ ($P = .0001$); with needle drugs, $r = -.07$ ($P = .0003$). The valence of these coefficients is a function of the directionality of the questions loading on each factor. In each case the valence is consistent with the hypothesis that increased drug use,

TABLE 3—Mean Drug Use Factor Scores for Three Suicide Questions

Question[a]		n	Cocaine/Crack[b]	Alcohol[b]	Marijuana[b]	Needle Drugs[c]
During the past 12 months, have you ever *seriously* thought about attempting suicide?	Yes	712	0.17[d]	0.28[d]	0.17[d]	−0.11[d]
	No	2148	−0.05	−0.09	−0.06	0.04
During the past 12 months, did you make a specific plan about how you would attempt suicide?	Yes	417	0.40[d]	0.35[d]	0.25[d]	−0.23[d]
	No	2473	−0.07	−0.06	−0.04	0.04
If you attempted suicide during the past 12 months, did that attempt result in an injury or poisoning that had to be treated by a doctor or nurse?	Yes	57	1.93[d]	0.66[d]	0.82[d]	−0.41
	No	2675	−0.04	−0.03	−0.01	0.02

[a]These questions were prefaced by the following statement: Some people sometimes feel so depressed and hopeless that they may even consider attempting suicide, that is taking some action to end their own life.
[b]Higher scores for the cocaine, alcohol, and marijuana factors represent greater frequency of use.
[c]Lower scores for the needle drugs factor represent greater frequency of use.
[d]Differences in mean scores are significantly different ($P < .01$) in these cells.

early onset of drug use, or both is associated with a greater tendency to think about or actually attempt suicide. This pattern of relationships was supported by comparison of mean drug factor scores as a function of responses to the individual suicide questions. Significant differences existed between mean factor scores for all but one case (needle drug factor and severity of suicide attempt) (Table 3). Correlation coefficients calculated between drug factor scores and the number of reported suicide attempts were as follows: cocaine/crack, $r = .29$ ($P = .0001$); alcohol, $r = .13$ ($P = .0001$); marijuana, $r = .11$ ($P = .0001$); and needle drugs, $r = -.09$ ($P = .0001$).

Discussion

The relationship between substance abuse and suicide ideation and behavior has been explored by a number of researchers. Substance abuse appears to be associated with more frequent suicide ideation and suicide attempts, particularly in retrospective studies among high-risk youth.[9] Our study generalizes these relationships to noninstitutionalized public school youth and further specifies the nature of the substance abuse–suicide relationship.

In this study the use of cocaine/crack was more closely associated with a self-reported incidence of attempted suicide than was use of alcohol, marijuana, or needle drugs. This effect may have been due to a differential influence produced by the substance of choice or to a tendency of individuals with a heightened susceptibility to the emotional conditions leading to attempted suicide to use cocaine/crack. Use of cocaine/crack, alcohol, or marijuana was significantly related to a student's report of seriously thinking about attempting suicide or making specific suicide plans.

A precise cause-and-effect relationship between drug use and suicide behavior cannot be established from these data. Information concerning previous life events, family violence, illness, and other potential confounding factors was not available in the NCYRBS data base. The results of this study do, however, agree with the findings of previous researchers linking substance abuse to adolescent suicide. Recognition of this relationship is important for health educators involved in designing intervention programs for high-risk youth as well as for the general school population. □

Delay in Ambulance Dispatch to Road Accidents

ABSTRACT

When a road accident occurs, the police communications officer, or 911 operator, generally receives the first call. If the caller reports injuries, the emergency medical services dispatcher is notified immediately; but if the caller is uncertain of injuries, the operator may wait. Most often an ambulance is not needed. However, in nearly 20% of fatal road accidents in Missouri, waiting for confirmation of need resulted in a delay of 5 minutes or more in the dispatch of an ambulance. (*Am J Public Health.* 1992;82:873–875)

Harold Brodsky, PhD

Introduction

In life-threatening road accidents, a call for emergency medical services (EMS) needs to go out quickly and unambiguously. Trauma is a "time-dependent disease," and basic life support may be needed soon after a crash.[1] Any factor that might delay an EMS arrival at a road accident where an injury has occurred should be a matter of concern.

A police communications officer or 911 operator usually receives the earliest notification of an accident. The police depend on the caller for information on possible injuries. If the caller specifies injuries, the EMS dispatcher is notified quickly and an ambulance may be sent out almost immediately. If the caller is vague, however, the police officer may wait before contacting EMS.

How often does a policy of waiting for confirmation of need result in the delayed dispatch of an ambulance to an injury accident? Many states do not require ambulance services to submit data on notification time, so there is no way of telling. Fortunately, Missouri has police and EMS records that can be used for this type of statistical analysis. However, in other respects, such as accident rate and police communications policy, Missouri appears to be typical of the United States and perhaps other Western nations.

Analysis of Dispatch Delays

Two data sources from Missouri are used here: fatal accidents between 1985 and 1988, and injury accidents in 1987. Details on the processing of these data are discussed elsewhere.[2] Estimates used here for delays are believed to be conservative, especially for injury accidents.

A 4-year record of fatal accidents shows that in 18.2% of the cases (nearly one out of five), EMS was notified 5 minutes or more after the police were called (Table 1). A 1-year summary of injury accidents involving ambulance transports shows that the probability of delay varies with the police-reported severity of injury. Police-reported severities of injury, by and large, are not reliable substitutes for clinical measures, but they can be used as an index of outward appearance. Generally, the less obvious the appearance of an injury, the more likely that dispatch of an ambulance will be delayed (Table 2).

The most reasonable explanation for delays of 5 minutes or more is vague calls to the police about injuries. A caller might be uncertain whether an ambulance is needed if injuries are not apparent. Injuries that are less likely to be apparent are among those classified by the police as less severe (Table 2).

Callers might also be vague about injuries if they did not stop to investigate before calling the police. Variables significantly associated with longer delays are land (urban vs rural), time (normal activity

	5	0.138632	.066491	4.35	.0371
Land × time	6	0.12065	.0541755	4.96	.0259

Note. Dependent variable is ambulance dispatch delays of 1 minute or less, relative to (or divided by) delays of 5 minutes or more.
[a]A copy of the data set and the control statements to run this analysis under SAS can be obtained from the author.

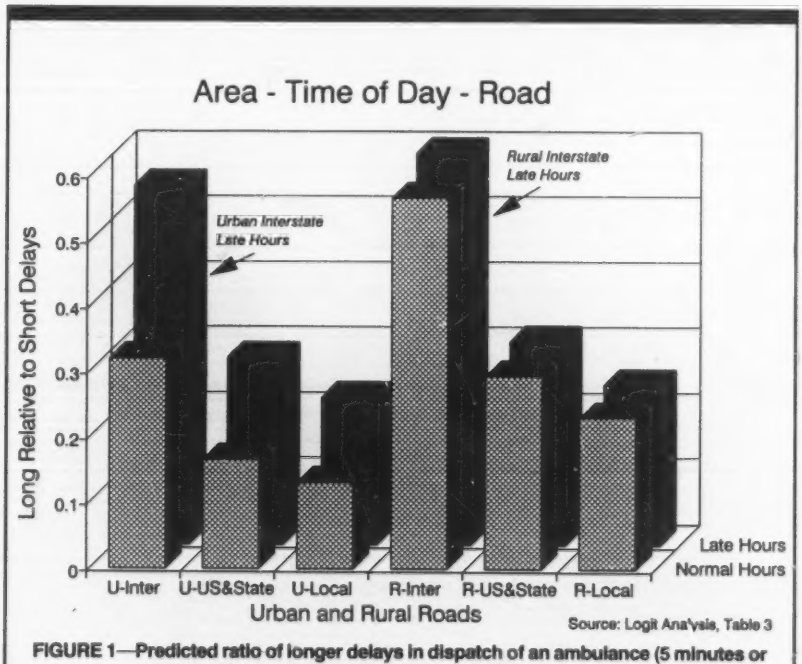

FIGURE 1—Predicted ratio of longer delays in dispatch of an ambulance (5 minutes or more) to shorter delays (1 minute or less) in fatal accidents in Missouri, 1985–1988, by road environment

hours of 7 AM to 11 PM vs late hours), and road (interstates, US and state highways, and local county roads and urban streets). The interaction between land and time indicates that during normal hours of the day, an urban environment has a lower probability of delay than a rural environment, but late at night, urban and rural environments have similar probabilities (Table 3 and Figure 1).

The highest probabilities of delay, regardless of time of day and area, are from the interstate road system. Calls about accidents on interstate highways may come from passersby who see the accidents but do not stop to investigate. A motorist might sense a danger in stopping and backing up on a high-speed interstate highway, especially late at night. The first call to the police, therefore, might not be specific about injuries. In contrast, if accidents occur on roads passing through populated areas, bystanders or motorists will usually check to see if there are injuries before calling. Nevertheless, late at night, even in an urban area (as the interaction variable seems to indicate), the first caller may report only having heard a loud crash.

Discussion

Police communications officers are currently the gatekeepers of emergency services in road accidents.[3] They are required to estimate the likelihood of injuries when a vague call is received. Most often an ambulance is not needed. The chance of any single road accident being life-threatening is small, and so the police may perceive that the risk involved in waiting for confirmation of need is also very small. Yet in almost one out of five fatal accidents in Missouri, the police were initially unaware of the severity of the injury, and a delay of 5 minutes or more occurred before they notified EMS.

Police communication policy on handling vague calls varies with locale. In some smaller cities in Missouri, EMS is apparently notified in all, or almost all, local road accidents—perhaps because it usually takes little time for an ambulance to be sent to the scene. In certain counties, the police officers notify EMS immediately if the crash occurs in a remote rural location, even if the caller is vague about injuries. These officers reason that if they wait for confirmation of need, it might take too long and EMS might arrive too late to do any good.

Some EMS managers in Missouri feel that in an uncertain situation, these basic decisions should be made by the

EMS dispatcher and not the police communications officer. EMS has several options. If an ambulance is available and another is in reserve, EMS may prefer to go out to a road accident even if the probability of need seems small. The ambulance could proceed at normal speed, without the use of emergency sirens, and remain alert to a probable recall.

Some say that ambulances could be dispatched more often when injuries are uncertain. Such a policy would reduce the number of communication delays in life-threatening road accidents. But at what cost? Apparently there are differences in opinion on this matter.

Because conditions vary locally, no blanket policy recommendation may be possible. At present, communications officers have little feedback on the overall consequences of their decisions. However, it is possible to link police communication data with emergency medical data, which makes it possible to monitor the effects of any change in policy on outcome and cost.

No one knows for sure how many lives could be saved or recoveries eased by the faster arrival of an ambulance. But no one will argue against the need for a rapid EMS response when lives may be in danger. □

Acknowledgments

Race, Belief in Destiny, and Seat Belt Usage: A Pilot Study

Israel Colón, PhD

ABSTRACT

A survey of 1063 individuals found that when belief in destiny was statistically controlled, differences in seat belt use by race disappeared. Thus, racial differences in seat belt use are statistically accounted for and might be explained by belief in destiny. Efforts to increase seat belt use should target minority groups rather than include them in broadbrush programs. Further, these efforts should take into account this important difference in motivation. (*Am J Public Health.* 1992;82:875–877)

Introduction

In the effort to increase seat belt usage, numerous strategies (legislation, educational campaigns, monetary incentives, etc.) have been employed with varying degrees of success. Of particular concern are racial and ethnic minority groups, who have lower rates of seat belt usage than Whites.[1,2] Additionally, Blacks have been found to be less responsive to efforts to increase use.[2]

Race per se (i.e., a physical attribute) certainly cannot explain differences in seat belt usage. One consideration that might be taken into account in targeting minority groups is differences in motivation. One possible difference in motivation is adherence to the concept of destiny. If one is strongly wed to the notion that the end of life is divinely decreed, efforts based on reason or logic will fall on deaf ears. Rotter[3] found that minority groups—Blacks and Puerto Ricans—were more fatalistic than Whites. In a study of seat belt use in families, Williams[4] found correlations between a measure of destiny and seat belt use by mothers and daughters. In another study, seat belt users identified themselves as fatalistic less often than nonusers.[5]

The purpose of this study is to assess the extent to which belief in destiny might explain lower seat belt usage among racial and ethnic minority groups.

Method

The study was carried out during February and March of 1988 in the city of Harrisburg, Pennsylvania, and its suburbs.

In line with the aim of quickly surveying a large number of people who were not being paid to participate in the study, a data entry sheet was developed resembling a data file (i.e., variables were represented in the columns and cases in the rows). Responses were directly entered into these data sheets. Thus, an interview could be completed in a matter of minutes.

A combination availability and purposive sample design was used. The greater Harrisburg area contains only

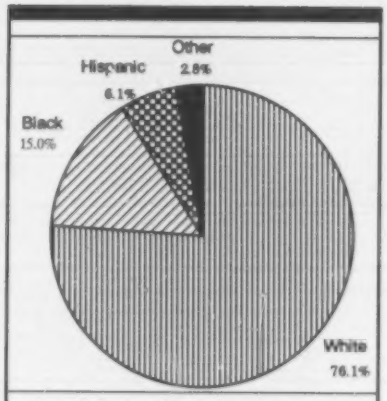

FIGURE 1—Distribution of race (n = 1063)

7.3% Blacks and Hispanics, and the purpose of this study dictated that these people be overrepresented in relation to their relative size in the population.[6] A probability sampling technique, short of using an extremely large sample, would not produce a sufficient number of minority group members to facilitate analyses. Consequently, two criteria were used in selecting participants: (1) maximization of variation—i.e., subjects were sought in a wide array of settings (shopping malls, a motor vehicle bureau, public and private offices, etc.); and (2) overrepresentation of minority group members—i.e., minorities were visually sought out for inclusion and their communities were canvassed.

In addition to demographic information, participants were asked whether they owned an automobile with seat belts that automatically fastened. Anyone who answered yes to this question was precluded from the study. Seat belt usage was operationalized by asking people to approximate the percentage of the time they used seat belts. To measure destiny, the following statement was read to participants: "There is no point in using seat belts since you can't change your destiny." Participants were given a 5 × 8-in card with a seven-point Likert scale, which ranged from *strongly disagree* to *strongly agree,* and were then asked to report their level of agreement with the statement.

Results

The sample was made up of 1063 participants: 690 females (64.9%) and 373 males (35.1%). The mean age of the sample was 38.3 years (SD = 17.1 years). The modal category for race was *White* (76.1%), with minority group members making up 23.9% of the sample (see Figure 1). The mean for seat belt usage ("what percent of the time do you use seat belts?") was 73.6% (SD = 34.2%), with a range running the full gamut (0% to 100%). In response to the statement, "There is no point in using seat belts since you can't change your destiny," the mean level of agreement was 2.2 (SD = 1.7), which corresponds to *disagree* on the seven-point Likert scale.

For purposes of data analysis, the variable for race was dichotomized into *White* and *non-White* categories. Non-Whites' level of agreement (mean = 2.46, SD = 1.9) was significantly greater than that of Whites (mean = 2.08, SD = 1.6) regarding the seat belt–destiny statement (t = 3.14, df = 1061, P = .0017). Non-White seat belt usage (mean = 66.8%, SD = 35.2%) was significantly and substantially lower than that of Whites (mean = 75.4%, SD = 34.1%).

To examine the relationship between race and seat belt usage while statistically controlling for belief in destiny, a two-factor analysis of variance model was used. In this analysis, the seat belt–destiny variable was collapsed into three categories (disagree, neutral, and agree). A summary of this analysis reveals that there is no significant interactional effect and that the only significant predictor of seat belt use is the destiny variable (see Table 1). It is thus apparent that the original difference by race in seat belt usage could be an artifact that disappears once belief in destiny is statistically taken into account.

TABLE 1—Summary of Two-Factor Analysis of Variance Predicting Seat Belt Use

Variable	df	Sum of Squares	Mean Square	F Ratio	P
Destiny	2	110133.29	55066.65	52.60	.0001
Race	1	1136.62	1136.62	1.09	.296
Destiny × race	2	3458.47	1729.24	1.65	.193
Error	1057	1107483.34	1047.76		

Discussion

The purpose of this study was to examine the relationship between race and seat belt usage vis-à-vis the belief in destiny. A multivariate model was used to examine simultaneously the contributions of race and belief in destiny in explaining reported seat belt usage. Differences in usage by race were statistically accounted for by differences in the belief in destiny.

Two limitations of this study are rather apparent: a nonprobability sample was used and seat belt usage was based on self-report. It has been demonstrated that reported use of seat belts is greatly inflated in comparison with observed use.[7,8] Given the exploratory nature of this study, reported use should be taken as an index rather than an estimate of actual use. Because this study was not intended to get actual use estimates but to explore the hypothesis relating race, belief in destiny, and usage, the present findings are certainly provocative and warrant further and more careful study.

Although this study is only exploratory, its findings suggest two points with implications for social policy. First, broadbrush strategies that do not take into account racial differences in motivation to use seat belts can have only limited success. Second, interventions based on logic or rationality appear to be inappropriate strategies with Hispanics and Blacks. Instead, programs might be developed in conjunction with churches in Hispanic and Black communities, where the church has an important voice. Although some may view such an approach as alien to American tradition and values, public safety and welfare suggest pragmatism over idealism. □

Work-Site Nutrition Intervention and Employees' Dietary Habits: The Treatwell Program

Glorian Sorensen, PhD, MPH, Diane M. Morris, PhD, RD, Mary K. Hunt, MPH, RD, James R. Hebert, ScD, Donald R. Harris, PhD, Anne Stoddard, ScD, and Judith K. Ockene, PhD

ABSTRACT

In a randomized, controlled study of the Treatwell work-site nutrition intervention program, which focused on promoting eating patterns low in fat and high in fiber, 16 work sites from Massachusetts and Rhode Island were recruited to participate and randomly assigned to either an intervention or a control condition. The intervention included direct education and environmental programming tailored to each work site; control work sites received no intervention. A cohort of workers randomly sampled from each site was surveyed both prior to and following the intervention. Dietary patterns were assessed using a semiquantitative food frequency questionnaire. Adjusting for work site, the decrease in mean dietary fat intake was 1.1% of total calories more in intervention sites than in control sites ($P < .005$). Mean changes in dietary fiber intake between intervention and control sites did not differ. This study provides evidence that a work-site nutrition intervention program can effectively influence the dietary habits of workers. (*Am J Public Health.* 1992;82:877–880)

Introduction

This paper presents the results of a randomized study testing the efficacy of Treatwell, a work-site nutrition intervention program designed to promote dietary changes associated with the reduction of cancer risk. This program focuses on two dietary goals of the National Cancer Institute: reducing consumption of fat to 30% of total calories and increasing consumption of dietary fiber to 20 to 30 g per day.[1] The study tested the hypotheses that there would be a significant decrease in calories from fat and increase in grams of fiber consumed by employees of the intervention work sites compared with employees of control work sites.

Methods

Sixteen work sites from central Massachusetts and Rhode Island were recruited to participate in the study, described elsewhere.[2] Work sites ranged in size from 300 to 1400 employees, and each had a cafeteria with a kitchen. The work sites, stratified by size and distribution of employees by gender, were randomly assigned to an intervention or control condition. At intervention work sites, programs such as classes and food demonstrations were targeted to individuals, and cafeteria point-of-choice labeling programs provided environmental support. In addition, programs were tailored to each work site through an employee advisory board, and eating pattern guidelines provided consistent messages across intervention activities (Appendix 1). No intervention was provided at the control work sites.

A questionnaire was distributed prior to the intervention in summer 1988 (time 1) to 275 employees randomly selected from each work site. Respondents were surveyed a second time at the end of the intervention period (time 2). This survey included a 67-item semiquantitative food frequency questionnaire (FFQ) developed and validated by Willett and colleagues.[3] Employee characteristics, including sex, age, education, ethnicity, occupation, and body mass index (BMI), were also assessed.

One work site assigned to the intervention group elected not to participate in the intervention. Nevertheless, dietary changes of employees of all eight companies assigned to the intervention were compared with those of employees at the control sites. This approach permitted estimation of the overall effectiveness of this program in work sites that agreed to participate, regardless of their "compliance" with the program.

Analyses of the major outcomes were based on repeated measures analysis of variance using the SPSS-X software program.[4] In analyses, employee effects were

Note. SD = standard deviation.
[a]None of the differences between treatment groups was found to be significant using analysis of variance.
[b]Education was measured on a six-category scale ranging from being less than high school graduate to having an advanced degree. The midpoint of each interval (in years) was used to estimate the mean.
[c]Body mass index = (weight in kg ÷ height in m^2).

nested within work-site effects. Mean values presented for each treatment condition represent the mean of the work-site mean values, thereby giving equal weight to each work site, which served as the unit of randomization and intervention.

Fat was expressed as a percentage of total calories because such a measure provides an intrinsic adjustment for caloric intake and directly addresses the public health message related to percent of calories as fat. It is a conservative measure in that the inflation of the numerator (i.e., fat calories) inflates the denominator by a numerically equivalent amount. Fiber values were transformed by the natural logarithm (ln) to comply with the assumptions of normality and homoscedasticity. Where summary mean scores are presented, we present the geometric mean.[5]

Results

A total of 3076 employees (70%, range: 52% to 93%) responded to the survey at time 1. Of those, 2258 (74%, range: 43% to 90%) returned the survey at time 2. Analyses were ultimately conducted on 2011 respondents for whom adequate data were available from both the time 1 and time 2 surveys.* No differences in baseline fat and fiber consumption, age, or sex were found between those who responded to both surveys and those responding only at time 1; however, those with more education were more likely to return the second survey (Table 1).

Significantly more intervention than control site employees reported that they were aware of a nutrition program at work and that they had attended classes at work on nutrition or weight management (see Table 2).

There were no statistically significant differences in baseline employee characteristics between the intervention and control work sites (see Table 3). Table 4 presents the relationship of these employee characteristics to total intake of dietary fat and dietary fiber (geometric mean), measured at baseline. As shown in the table, total dietary fat varied significantly by age, sex, and BMI; total dietary fiber varied significantly by age, sex, and education. The variability by work sites in mean changes in fat and fiber consumption are shown in Table 5.

There was a treatment-by-time effect for total dietary fat, and the decrease in

*At time 1, 211 questionnaires (7%) were eliminated from the analyses because there were more than 10 blank responses on the FFQ or because the reported daily caloric intake was less than 600 kcal or more than 4000 kcal, suggesting possible reporting errors. Similarly, 123 records were not included in the time 2 analyses for these reasons. Further information about the analyses is available upon request.

TABLE 4—Mean Baseline Level of Dietary Fat and Dietary Fiber by Employee Characteristics and Results of ANOVA Testing of Differences in Means

[a]Geometric mean for total dietary fiber intake derived by exponentiating the log value.

mean dietary fat was greater in intervention than in control work sites (Table 6). The decrease in total dietary fat was not affected by age, education, sex, BMI, or ethnicity (not shown in table). There was suggestion of a larger increase in mean dietary fiber among intervention than among control work sites. However, differences in total dietary fiber (ln) remained nonsignificant despite the inclusion of age, sex, education, BMI, and ethnicity in the model. Table 6 also presents the mean changes in fat and fiber after controlling simultaneously for age, sex, and education—the variables most likely to influence the effect of the intervention.

Discussion

This study is one of the first randomized controlled studies of a comprehensive work-site intervention promoting dietary change to reduce cancer risk.[6] The educational messages emphasized two changes: eat less fat and more fiber. The results indicate that the program was efficacious in reducing fat intake among employees of the intervention work sites.

There are many challenges inherent in work-site-based intervention research. In this study, three intervention sites experienced labor strikes and one moved to another location; similar changes did not occur in any of the control sites. One work site randomized to the intervention withdrew from the program although it did permit administration of the second survey. Thus, the program's overall effect was diluted by sites not fully implementing the program. Finally, the aim of 30% or less of calories from fat was not achieved. Nonetheless, we did observe an intervention effect for fat intake despite fluctuations in the degree to which the intervention was implemented.

The FFQ was used in this study because it can be self-administered, can be processed relatively rapidly and at a low cost, and can provide estimates of specific nutrient levels. However, it is subject to recall bias because respondents must average their intake of specified foods over a 12-month period. Assuming there is no intervention-related measurement bias, the FFQ can provide a reliable estimate of nutrient levels to be compared within this study between baseline and follow-up. Because the FFQ is associated with a bias in nutrient intake estimates, the results cannot be compared reliably with estimates derived from other types of dietary assessments. The lack of a significant fiber effect may also be a function of the measurement limitations, given that the FFQ may not provide a sensitive assessment of dietary fiber intake.[7]

In conclusion, this study provides some of the first evidence from a randomized controlled trial that a nutrition intervention program in work sites can have a significant impact on workers' eating behaviors. This employee-driven intervention program integrated individual behavioral change strategies with social and environmental support to produce dietary changes that are associated with reduced cancer risk. With growing evidence of the health implications of dietary habits, such strategies must be identified to promote healthy eating patterns not only among those at high risk but also among the entire population. □

APPENDIX—Treatwell Eating Pattern Guidelines

TRIM FAT

Choose fish, skinned turkey and chicken, and trimmed lean red meat. Keep the amount at six ounces or less, cooked, a day.
Choose low-fat dairy products: skim, 1%, or 2% milk; low-fat yogurt; ice milk; and low-fat cheeses.
Use half the amount of fat or oil you normally use in cooking and baking, and at the table.

ADD FIBER

Eat at least one serving of high-fiber cereal every day.
Eat one or more servings of fruit at each meal and for snacks.
Eat one or more servings of vegetable at lunch and dinner.
Eat at least one of these foods at each meal:
Whole-grain bread, rice and/or pasta, potato
Dried beans, peas, or lentils

Health Status of Older Male Prisoners: A Comprehensive Survey

Patricia L. Colsher, PhD, Robert B. Wallace, MD, Paul L. Loeffelholz, MD, and Marilyn Sales, RN

ABSTRACT

Although prison populations remain predominantly young, the number of older inmates in state and federal correctional facilities has been increasing. This report describes the results of a health survey of 119 male inmates 50 years of age and older residing in Iowa state correctional facilities. Subjects' disease history included hypertension (40%), myocardial infarction (19%), and emphysema (18%). Most participants (97%) had missing teeth, 42% had gross physical functional impairments, and 70% smoked cigarettes. These findings have implications for health care provision and release planning. (*Am J Public Health.* 1992;82:881–884)

Introduction

The number of older inmates in state and federal correctional facilities has been increasing as a result of the aging of the general population and changes in arrest and sentencing patterns.[1–5] Although older persons still account for less than 4% of the US inmate population, there is concern about their impact on corrections systems. It has been suggested that older inmates may require additional health care services; assistance with personal care; special dietary, educational, rehabilitative, and recreational services; or modifications in the physical environment.[1,6–9] Concerns have also been raised about the need for special services upon parole or discharge.[9–11] However, because relatively little is known about the health and functional status of older inmates,[1] planning for this population is difficult. This report describes a population-based health survey of older inmates in Iowa correctional facilities.

Methods

Respondents

The respondents were 119 men (81% of the target population) aged 50 years and older who were residing in seven Iowa state correctional facilities housing men between June and December, 1989. Nonparticipation was most often the result of refusal by the inmate (23 of 29 nonparticipants). There were too few women residing in the one women's facility (n = 10) to tabulate here. The demographic characteristics of participants are shown in Table 1.

Interview Procedures and Measures

Letters describing the study were distributed to inmates, who returned postcards to investigators if they wanted to participate. Inmates were interviewed in person at the prisons; interviewers used a standardized questionnaire that required 90 minutes to administer. Interview contents are summarized in Appendixes 1 and 2.

Corrections staff were nearby but did not participate. Each participant received $5.00 compensation. The study was approved by the University of Iowa's institutional review board.

Statistical Analyses

Initial analyses[24] examined the distributions of measures according to age group (50 to 59 years, 60 years and older), using analysis of variance and chi-square for tests of statistical significance, as appropriate. Measures of cognitive function were adjusted for educational attainment.

Results

Table 2 shows the age group–specific and overall percentages of specific illnesses reported. The most common chronic illnesses were arthritis, hypertension, ulcers, prostate problems, and myocardial infarction. Rates were typically higher among inmates aged 60 years and older than among those aged 50 to 59 years.

Measures of age group–specific and overall health and functional status are presented in Table 3. Although almost 65% rated their health as excellent or good, almost half reported that their health had worsened since incarceration. Chest pain was reported by 61%, but fewer than 8% had a history of angina.[15] Fewer than 3% had all their teeth. Although 42% reported limitations in gross physical functional status, only 11% had limitations in routine self-care activities. Examination of the age group–specific measures indicates that participants aged 60 years and older were more likely to experience incontinence ($P < .01$), report hearing problems ($P < .05$), and have difficulty

[a]Values in parentheses are standard errors of the mean.

hearing normal voices ($P < .01$), than were those aged 50 to 59 years.

Psychobehavioral and social measures are summarized in Table 4. Participants typically rated their own memory and cognitive function as excellent or good, and of the 8 items on the mental status screening examination, they had a mean of 7.0 correct. Although older men were somewhat less likely than younger men to rate their own cognitive function as excellent or good ($P < .1$), there were no systematic differences in performance measures of cognitive function. Depressive and anxiety symptoms were common, but psychotic symptoms were less frequently reported. Older men reported significantly more offspring ($P < .05$), but there were no differences in visitation patterns. Only 37% of the men had visitors during the month prior to the interview, and most wished they had more.

Most inmates (69.8%) were current cigarette smokers, and 18.5% were former smokers. Current smokers consumed a mean of 23.0 cigarettes (SD = 13.6) per day. Almost all inmates (96.6%) had a history of alcohol consumption, and 45.4% described themselves as having been heavy drinkers; 29.4% reported illicit drug use.

Discussion

This report describes the health and functional status of older inmates in Iowa state correctional facilities. Although chronic illness was common and many inmates reported limitations in gross physical functional ability, most inmates were able to perform routine self-care activities and described their own health as excellent or good. There was little evidence of cognitive impairment. Sizable social networks were described, but visits were not common.

Self-reported rates of lifetime substance use were high and may have implications for health care. The high rates of smoking (over twice the national average)[25] may contribute to the respiratory symptoms and illnesses, cardiovascular

conditions, and cancer found among this population; thus, smoking cessation programs appropriate to the prison environment should be developed. A history of heavy drinking was four times as common among these inmates as it was in a population-based study of older Iowans.[26] In that study, a history of heavy drinking was strongly associated with increased morbidity and mortality. The effects of illicit drug use on older persons remains largely uninvestigated. However, the absence of substantial alcohol and other substance abuse in the prison system could have a mitigating effect on subsequent disease occurrence.

The finding of increased rates of incontinence, sensory impairment, and flexibility impairment suggests that corrections departments may need to modify the physical environment of prisons that house large numbers of older inmates and provide special programming.[1,13] The provision of specialized equipment, however, may raise issues of limited resources and priority setting.

Several limitations should be noted in these findings. First, the cohort is small although it does include most older male inmates in Iowa state correctional facilities. Second, some misclassification may have been introduced by the use of self-reported history of chronic conditions. Third, Iowa has lower crime and incarceration rates than do many other states,[27] and the prisons in Iowa are relatively small. Moreover, inmates in Iowa facilities may have different levels of access to or use of health care services than inmates in other states. Thus, the findings reported here should be replicated in other prison systems, especially those with larger numbers of minority inmates and women. □

APPENDIX 1—Summary of Demographic, Health, and Functional Status Measures

Demographic characteristics
- Age
- Educational attainment
- Race
- Marital status
- Criminal history

General health status
- Self-reported lifetime history of physician diagnosed illness
  - myocardial infarction, stroke, hypertension, cancer, diabetes, arthritis, asthma, emphysema, ulcers, cirrhosis, venereal disease, prostate problems
- Symptoms and complaints in past year
  - dry or itching skin, pain in legs at night, indigestion, fallen arches, bunions or corns on feet, other foot problems, trouble with fingernails or toenails, joint pain, morning joint stiffness
- Enumeration of major illnesses
  - myocardial infarction, stroke, hypertension, cancer, diabetes
- Respiratory symptoms[12]
  - shortness of breath, coughing, phlegm production
- Self-perceived health status
  - as compared with age mates,[13] as changed since incarceration
- Sleep problems[14]
  - trouble falling asleep, wake during night, wake too early, feel rested in morning, need to nap during day
- London School of Hygiene Cardiovascular Questionnaire[15]
- Urinary incontinence[14]
- Low back pain in past year[14]
- Self-rated vision function[16]
- Self-rated hearing function[16]
- Self-reported height and weight
- Tooth loss[14]

Physical functional status
- Gross physical function[17]
  - walk a half-mile, walk up stairs, do heavy work
- Instrumental activities
  - fill out forms and requests, handle own canteen account, clean cell, make telephone calls
- Routine self-care activities[18]
  - bathe, dress, groom, toilet, eat, walk across small room, transfer from bed to chair
- Isolated movements[19]
  - push heavy objects, stoop, lift 10 pounds, reach arms above shoulders, write, handle small objects, stand in place for 15 minutes, get up from chair, stand on one foot, pick up object from floor

APPENDIX 2—Summary of Substance Use and of Psychobehavioral and Social Measures

Substance use[16]
- Tobacco
  - cigarettes, cigars, pipes, smokeless tobacco
- Alcohol[14]
  - whether alcohol ever consumed, history of heavy drinking
- Illicit drugs
  - stimulants, sedatives, opiates, marijuana, hallucinogens

Psychobehavioral function
- Cognitive function
  - mental status screening examination,[20] 20-item memory performance test,[14] self-rated memory,[14] self-rated cognition
- Affect and psychiatric symptoms
  - Center for Epidemiologic Studies Depression Scale,[21] anxiety symptoms,[14] loneliness,[22] psychotic symptoms[23]

Social network/style[14]
- Number of offspring
- Number of close relatives
- Number of friends inside prison
- Number of friends outside prison
- Number of visitors in past month
- Desire for more visitors
- Tendency to discuss problems with others
- Preference for solitary activities

A Neonatal Hepatitis B Surveillance and Vaccination Program: New York City, 1987 to 1988

Kelly J. Henning, MD, Daphna M. Pollack, MPH, and Stephen M. Friedman, MD, MPH

ABSTRACT

From July 1987 to June 1988, 1030 pregnant women with hepatitis B were reported to a New York City surveillance program. Among 832 infants under follow-up, the coverage rates for combined hepatitis B immune globulin and vaccine doses 1, 2, and 3 were 84%, 77%, and 59%, respectively. Infants covered by Medicaid and uninsured Black and Hispanic infants were significantly less likely to be completely vaccinated. An estimated 160 cases of chronic hepatitis B infection were prevented among infants enrolled in the program. Strategies are needed to improve vaccine coverage among hard-to-reach groups. (*Am J Public Health.* 1992;82:885–888)

Introduction

Hepatitis B virus (HBV) transmission from mother to infant during the perinatal period is highly efficient.[1–4] If the infant is not infected in the postnatal period, subsequent exposure to the mother or to other HBsAg-positive family members can lead to infection and chronic carriage.[5,6] Treatment of infants born to HBsAg-positive mothers with hepatitis B immune globulin (HBIG) and hepatitis B (HB) vaccine results in an 85% to 95% reduction in the carrier state.[7–9]

Women at high risk for hepatitis B carriage include women of Asian or Pacific Island descent, women born in Haiti or sub-Saharan Africa, and women who are intravenous drug abusers. In 1986, almost 2500 infants were born to high-risk mothers in New York City.[10] In the same year, the New York City Department of Health (NYCDOH) began a surveillance and vaccination program for HBsAg-positive pregnant women and their newborns.

Methods

The surveillance system for HBsAg-positive pregnant women included both active and passive components. Active surveillance targeted 13 New York City hospitals (8 municipal and 5 voluntary) serving high-risk populations. Yearly, about 40 000 births, representing 30% of all births in the city, occurred at these 13 hospitals. Five of the hospitals served large Asian communities. NYCDOH field workers reviewed hospital laboratory logs monthly and collected identifying information for HBsAg-positive pregnant women. Passive reporting sources included Maternity Infant Care, a New York State and federally funded family planning project; a large health maintenance organization with 895 000 subscribers; private physicians; and nonprogram hospitals.

NYCDOH workers contacted the HBsAg-positive women by telephone, letter, or home visit. A questionnaire was administered and women were counseled (in English, Spanish, Chinese, French, or Creole) regarding HBV transmission, the importance of screening household contacts, and the need for neonatal HB vaccination.

To facilitate administration of HBIG and the first dose of HB vaccine, all women enrolled in the program were given a letter from the NYCDOH stating their surface antigen status. Women were encouraged to take this letter to the hospital at the time of delivery. An infant was considered to have been given HBIG and vaccine dose 1 if a form documenting administration was received by the program or if the mother could clearly describe the administration of vaccine. Each infant was then followed, via multiple telephone calls to the mother and to the infant's caregiver, to ensure vaccination at 1 and 6 months of age. Infants for whom receipt of vaccine dose 3 could not be documented by 18 months of age were considered lost to follow-up.

The surveillance program was budgeted at less than $200 000 per year; screening of the pregnant women, provision of HBIG, and provision of the first dose of HB vaccine were not covered by the program.

Statistical analysis was done using standard microcomputer software (EpiInfo, Centers for Disease Control) and exact confidence intervals for relative risks were calculated using the methods of Thomas and Gart, where appropriate.[11]

The authors are with the New York City Department of Health, Bureau of Immunization, Epidemiology and Prevention Services. Kelly J. Henning is also with the US Centers for Disease Control, Division of Field Epidemiology, Epidemiology Program Office, Atlanta, Ga.

TABLE 1—HBIG and Vaccine Coverage by Dose for 832 Infants, Hepatitis B Surveillance and Vaccination Program, New York City, July 1987 to June 1988

HBIG/Vaccine Dose	Infants Receiving HBIG/Vaccine	
	No.	%
HBIG	706	85
1	810	97
2	738	89
3	554	67
HBIG + 1	702	84
HBIG + 1 + 2	637	77
HBIG + 1 + 2 + 3	492	59

Results

In the 1-year period from July 1, 1987, through June 30, 1988, 1030 HBsAg-positive women were identified. The 13 participating hospitals screened 20 108 pregnant women; 488 (2.4%) were HBsAg positive. Three hundred forty-two HBsAg-positive women were reported from passive surveillance sources. The remaining 200 HBsAg-positive women were identified in the postpartum period and reported to the NYCDOH shortly after delivery (median, 10 days).

The study population consisted of 830 (81%) of the 1030 positive women. Reasons for exclusion from further study were as follows: 89 women did not respond to health department calls or letters, 50 provided insufficient locating information, 30 moved before delivery, 26 seroconverted to antigen-negative status before delivery, and 3 aborted or miscarried.

The 830 women delivered 832 infants. The combined HBIG and vaccine dose 1, 2, and 3 coverage rates were 84%, 77%, and 59%, respectively (Table 1). Delivery of HBIG and three doses of vaccine was similar among infants of women identified during the antepartum and postpartum periods (61% vs 56%, $P = .18$). The majority (80%) of infants received HBIG and the subsequent vaccine doses within the recommended dosage schedule.[12]

Questionnaires were completed on 670 (81%) of the 830 HBsAg-positive women. Vaccine completion varied by maternal race/ethnicity, maternal birthplace, and health insurance (Table 2). Infants of Black and Hispanic women were 24% and 37% less likely, respectively, to complete the series than were Asian infants. Infants of women who were Medicaid recipients were almost 30% less likely to complete the series than were infants covered by private insurance.

To evaluate health insurance as a possible confounder for the racial differences observed, vaccine completion rates by maternal race were stratified by health insurance (Table 3). Vaccine completion by race among women with private insurance or Medicaid was similar; however, in

the uninsured category, infants of Black and Hispanic women remained much less likely to complete the vaccine series than were Asian infants.

To evaluate the impact of this program, we compared completion rates for infants who received the first vaccine dose at the 13 program hospitals with those who received the first dose at nonprogram hospitals. Although 373 (73%) of the 514 infants who received dose 1 at program hospitals went on to complete the series, only 68 (59%) of the 116 infants who received dose 1 at nonprogram hospitals did so (relative risk = 1.24, 95% confidence interval = 1.05, 1.46). This difference persisted after we adjusted for maternal race and health insurance coverage.

We used the following assumptions to estimate the number of cases of chronic HBV infection prevented: (1) a 25% HBeAg positivity rate for the HBsAg-positive women[2,13]; (2) in the absence of vaccination, a 90% HBV transmission rate to infants of HBeAg-positive women, with a 90% chronic carriage rate for these infants[1,2]; (3) in the absence of vaccination, a 20% chronic carriage rate for infants born to HBeAg-negative women; and (4) a vaccine efficacy of 92%.[3,4,13] Among the 493 infants who completed the vaccine series, we estimate that 174 cases of chronic HBV infection would have occurred had they not been vaccinated. We expect that vaccination prevented 160 (92%) cases.

Discussion

This is the first report of a large surveillance system and vaccination program for hepatitis B–infected pregnant women and their newborns in the continental United States.

A primary aim of the program is to assist in delivery of the second and third dose of HB vaccine. Although the second dose of vaccine was administered to 89% of the infants enrolled in the program, only 67% received the third vaccine dose. A similar decline was noted among Asian and Pacific Island women who received county medical services in California.[13] In the New York City program, as in the California study, most infants without a documented third dose of vaccine were lost to follow-up. Because some of these infants may have completed the vaccine series elsewhere, the overall completion rate of 59% is likely to be an underestimate. However, many infants lost to follow-up had been receiving care at public clinics and hospitals and would have been unlikely to complete the series at private sites.

Method of health care payment explained most of the differences in vaccine completion rates. Medicaid-insured infants and uninsured Black and Hispanic infants had very low vaccine completion rates. Medicaid reimbursement in New York State falls 60 cents short of vaccine cost, does not adequately cover the cost of vaccine administration, and requires months for release of funds—all barriers to physicians caring for infants requiring HB vaccination. Improvement of vaccine completion will require increased Medicaid reimbursement.

The racial differences noted among uninsured mothers probably reflect socioeconomic differences. More than 95% of the uninsured Asian and White mothers gave birth at private hospitals; these women may be in a higher socioeconomic group than the uninsured Black and Hispanic mothers, most of whom delivered in public hospitals. Intensive follow-up and ready access to free vaccine may improve coverage rates for infants born in public hospitals. Additional strategies to improve completion rates include providing documentation of HB vaccine on the immunization card and incorporating HB vaccine into routine childhood vaccination schedules. HB vaccine coverage rates as high as 75% to 95% have been achieved when HB vaccine is administered with other childhood vaccines.[14–17]

In 1988, the Immunization Practices Advisory Committee recommended universal screening of all pregnant women for HBsAg.[12] In response, New York State passed a law, which took effect in May 1990, mandating universal screening of all pregnant women.[18] Future directions for the program include (1) administration of the second and third dose of HB vaccine at 2 and 6 months of age, concomitant with the diphtheria-tetanus-pertussis vaccine, for those vaccinated at city clinics; (2) HB surface antibody testing at 12 months; and

(3) provision of HBsAg screening and HB vaccine to family contacts of HBsAg-positive pregnant women.

The NYCDOH program was designed to establish surveillance in hospitals that serve women at highest risk for hepatitis B carriage. Therefore, the findings reported here do not reflect all HBsAg carrier mothers in New York City. However, we believe these findings may apply to other large, diverse cities in the United States. Health departments can assist physicians and patients by coordinating the transfer of information between physician groups, providing education to HBsAg-positive women, and ensuring follow-up of infants, particularly those in hard-to-reach groups. □

Acknowledgments

Preliminary results of this study were presented at the 39th Annual Conference of the Epidemic Intelligence Service, Atlanta, Ga, April 23–27, 1990.

The authors wish to acknowledge Dr Ismat Aziz for her work in the early stages of the program and Drs Robert Gunn and Harold Margolis for their comments on the manuscript. We also thank Kim Mealing for her technical assistance.

Physician and Infection Control Practitioner HIV/AIDS Reporting Characteristics

ABSTRACT

We surveyed a random sample of South Carolina physicians and infection control practitioners about the reporting of human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) cases. Of physicians surveyed, 79% indicated that HIV infection as well as AIDS should be reported by name. The following characteristics were associated with those physicians who do not report AIDS cases: not feeling responsible for reporting, not reporting a case perceived to have been reported in another state, believing that information required for reporting is not on the chart, and residing in an urban setting. Targeted education can address these underreporting factors. (*Am J Public Health.* 1992; 82:889–891)

Introduction

Reporting of acquired immunodeficiency syndrome (AIDS) is essential to understand disease transmission patterns and target preventive programs.[1–4] Reporting also affects state funding because disbursement of federal funds for several human immunodeficiency virus (HIV)/AIDS prevention and treatment programs is based on the annual number of cases reported.[5] To inquire about AIDS reporting practices, the South Carolina Department of Health and Environmental Control (DHEC) conducted a statewide survey of physicians and infection control practitioners (ICPs). Topics covered in the survey included the number of AIDS cases cared for, reporting attitudes and practices, and services DHEC could provide to facilitate reporting.

In South Carolina, AIDS has been reportable since 1982. HIV infection without AIDS has been reportable from physicians, hospitals, and laboratories since 1986. As of June 30, 1991, there were 1396 cases of AIDS and 5150 cases of HIV infection reported in South Carolina. Of the 1396 AIDS cases, 24 (1.7%) were in children younger than 13 years of age. With an annual AIDS incidence rate of 9.4 per 100 000 (June 1990 through May 1991), South Carolina ranked 23rd in the nation.[6]

Methods

In spring 1989, after implementation of active AIDS surveillance, the DHEC survey was mailed to (1) all physician specialists in the fields of infectious diseases, pediatric allergy/infectious diseases, hematology/oncology, and pulmonary medicine listed in the South Carolina Medical Association Directory; (2) an 18% random sample of the states' 1712 primary care internists, and family and general practitioners; and (3) ICPs from all inpatient facilities licensed by DHEC, military, and Veterans Administration hospitals. Physicians who identified themselves as ICPs were analyzed with ICPs (most of whom, in South Carolina, are nurses). Due to the small number (24) of reported pediatric AIDS cases, primary care pediatricians were not surveyed.

Three mailings of the questionnaire were made under different cover letters to enhance the response rate. There were 32 (11%) substitutions on the random sample for physicians who had retired or moved to another state since the list was compiled in the previous year. Chi-square for trend and prevalence ratios were calculated using Epi Info[7] software. SAS[8] software was used for backward stepwise logistic regression.
